M. JANSSEN has addressed to the French Academy of Sciences the following letter, on the principal consequences to be drawn from his observations on the solar eclipse of 12th December last; it is dated Sholor, December 19, 1871:—"I had the honour," he says, "of sending you on the very day of the eclipse a few lines to inform the Academy that I had observed the eclipse under an exceptional sky, and that my observations led me to assume a solar origin for the Corona (see NATURE, vol. v. p. 190). Immediately after the eclipse I was obliged to busy myself with the personal and material arrangements for my expedition into the mountains, and hence I have been unable to complete any detailed account, but I take advantage of the departure of this courier to give some indispensable details as to the announced results. Without entering into a discussion, which will form part of my narrative, I shall say, in the first place, that the magnificent Corona observed at Sholor showed itself under such an aspect that it seemed to me impossible to accept for it any cause of the nature of the phenomena of diffraction or reflection upon the globe of the moon, or of simple illumination of the terrestrial atmosphere. But the arguments which militate in favour of an objective and circumsolar cause, acquire invincible force when we inquire into the luminous elements of the phenomenon. In fact, the spectrum of the Corona appeared in my telescope, not continuous, as it had previously been found, but remarkably complex. I detected in it, though much weaker, the brilliant lines of hydrogen gas, which forms the principal element of the protuberances and chromosphere; the brilliant line which has already been indicated during the eclipses of 1869 and 1870, and some other fainter ones; obscure lines of the ordinary solar spectrum, especially that of sodium (D); these lines are much more difficult to perceive. These facts prove the existence of matter in the vicinity of the sun; matter which manifests itself in total eclipses by phenomena of emission, absorption, and polarisation. But the discussion of the facts leads us still further. Besides the cosmical matter independent of the sun which must exist in its neighbourhood, the observations demonstrate the existence of an excessively rare atmosphere, with a base of hydrogen, extending far beyond the chromosphere and protuberances, and deriving its supplies from the very matter of the latter—matter which is projected with so much violence, as we may ascertain every day. The rarity of this atmosphere at a certain distance from the chromosphere must be excessive; its existence, therefore, is not in disagreement with the observations of some passages of comets close to the sun."

We earnestly call the attention of all men of science who may have influence with the French Government, to the letter on behalf of *Elisée Reclus* by Mr. H. Woodward, which will be found in another column.

We have to record the death of the Rev. Canon Moseley, F.R.S., on Saturday last in his 71st year. Born in 1801, he went to St. John's College, Cambridge, where he graduated seventh wrangler in 1826. He was for a time Professor of Natural Philosophy and Astronomy at King's College, London, and was afterwards appointed one of Her Majesty's Inspectors of Schools, and was a member of the Ordnance Select Committee. Canon Moseley was well known for his writings on various physical subjects, in particular on the phenomena connected with the freezing of water, and the molecular constitution of glacial ice.

THE *Photographic News* notices the death of one of the most eminent continental photographers, Johannes Grasshoff, of Berlin, at the early age of thirty-six. At the recent exhibition of the Photographic Society in Conduit Street, his studies were among those most admired in the whole collection, and not least his group of thirty different pictures from one and the same

model. Like some others of the most successful photographers, his education was that of an art student, and he was known as a clever painter before he became a skilful photographer.

It will be recollected what a warm discussion was raised in the French Academy of Sciences before the late war by the proposal to enrol Mr. Darwin among its corresponding members. The proposal was at that time postponed, but his name has now been placed first on the list for the forthcoming election of a Corresponding Member in Zoology, and he will, therefore, no doubt receive the honour. His supporters are MM. Milne-Edwards, Quatrefages, and Lacaze-Duthiers.

At the meeting of the Royal Geographical Society on Monday evening last, Lieutenant Dawson, R.N., was introduced as the leader of the party organised to attempt the relief of Dr. Livingstone. Mr. W. O. Livingstone, a son of the explorer, born in the neighbourhood of Lake N'gami, is to accompany the party. An application to the Treasury for a grant of money to aid the expedition has been unsuccessful. Should this decision be a final one, the undertaking must therefore depend entirely on private subscriptions; but we are happy to see that the subject is already being warmly taken up in many of the larger towns in the country, and the sum of 1,700*l.* was announced as having been raised by Monday evening last. Since then a public meeting has been held at Glasgow, at which 200*l.* was subscribed, and one will probably be held in London, under the auspices of the Lord Mayor.

The subscription raised as a Memorial Fund to the late Mr. Alder of Newcastle now amounts to about 300*l.* This is considerably less than the amount it was thought might have been raised, though sufficient to carry out in a limited form the original suggestions as to its appropriation. The Committee recommend that it should be invested in the names of trustees, and should serve as the foundation of a Scholarship in Zoology, or other branch of Biology, bearing Mr. Alder's name, in the New College of Physical Science in Newcastle; the transfer to be coupled with such stipulations as to the teaching of Biological Science as may be agreed upon.

THE editor of *Les Mondes* calls attention to the manner in which scientific chairs have been disposed of in France, not so much with the object of "finding men to fill the vacant places as places for the *protégés* or favourites of the moment." On the death of M. d'Archiac, the chair of palæontology in the Museum of Natural History at Paris was given to M. Lartet, a palæontologist of world-wide renown, but too advanced in years and of too feeble health to permit him to give a single lesson. On the death of M. Lartet, although there are a large number of good palæontologists in France, it was all but decided, from motives of private convenience and patronage, to abolish the chair, its maintenance being secured by a majority of two votes only. The appointment has now been made to the professorship of M. Albert Gaudry, late assistant to Prof. d'Archiac, and author of "*La Géologie et la Paléontologie de l'Attique*," an appointment which will give general satisfaction.

THE *Engineer* states that the French Government, impressed by the want of thorough geographical instruction, have under consideration a plan for a Geographical Institute, on a scale which has never before been attempted. The proposed Institute is to include all the means and accessories of geographical education in its widest acceptance—books, maps, charts, globes, instruments, collections of natural objects, &c.—and to include a staff of professors and teachers of the highest grades. The naval dépôt of charts and plans will form one of the departments of the new Institute, which promises to be of eminent service, not only to France, but to the whole of Europe, for, should it be established on the scale proposed, there is little doubt that it will give an impulse to geographical study throughout the civilised world.

THE Massachusetts Society for Promoting Agriculture will award on the 1st of March next two prizes of 300*dols.* and 200*dols.* respectively to the two best establishments in the State for the culture of fishes for food, all competitors for which must send in their names and addresses to the secretary of the Society, Edward N. Perkins, 42, Court Street, Boston. The committee of award will consider the number of species of fishes cultivated, the number of individuals, and their size and condition, the number of eggs hatched in the establishment, and of young reared from them, the neatness and economy of the establishment, and the excellence of the fixtures.

DR. STIMPSON, the secretary of the Academy of Sciences of Chicago, left Baltimore in the steamer of the 15th of December for Key West, for the purpose of making explorations and collections in the Florida waters, partly with the object of replacing that portion of the collection of the Chicago Academy lost by the fire. It is expected that he will take charge of the dredging operations of the United States Coast Survey steamer *Bibb*, while she is employed in selecting a line for the submarine cable which is to be laid for the International Cable Company between Cape San Antonio, Cuba, and some point on the coast of Yucatan.

WE learn from the *Gardeners' Chronicle* that among the disastrous losses occasioned by the Chicago fire, the very valuable Entomological Collection of the late Dr. Walsh was totally destroyed. The *Canada Farmer* states that after the death of the eminent entomologist, the collection became by purchase the property of the State. It was not only very extensive, but the specimens were arranged and labelled with great care and accuracy; and it will be many years before another can be collected to replace it.

THE first number of the Journal of the Anthropological Institute of New York, an institution newly organised upon the base of the former Ethnological Society of that city, is published. In the change the scope of the society has been greatly enlarged, and many of the difficulties attendant upon the maintenance of the old organisation have been obviated. Several papers of more or less interest are to be found in this first number, and there is little doubt that the new society will occupy a prominent place in advancing knowledge in the world.

MR. STEPHEN T. OLNEY, a well-known botanist, resident at Providence, Rhode Island, has just published a list of the Algae of Rhode Island, as collected and prepared by himself. In this he enumerates twenty-four species of melanosperms, or olive-coloured algae; forty-four of rhodospersms, or red algae; and twenty-five of the chlorospersms, or green algae, making ninety-three species in all. The remaining forms, principally microscopic, enumerated by him, and including zygnemaceæ, desmidiæ, and diatomaceæ, bring the number up to 189. Of most of these Mr. Olney possesses duplicates, which he will be happy to dispose of in exchange.

THE second volume of the "Annals of the Dudley Observatory," edited by its director, G. W. Hough, has just made its appearance, and consists of a report of the meteorological observations made at the observatory from 1862 to 1871. Its value is enhanced by its embracing the hourly records of the barometer (automatically printed) for a continuous period of five years, made by means of a very efficient apparatus invented by the director, and now used in numerous places, among others, in the office of the Signal Service at Washington. An appendix to the report contains miscellaneous communications upon the galvanic battery, the total eclipse of the sun of August 2, 1869, and the meteoric showers of 1867, &c.; and the whole book must be considered a very valuable contribution to physical science.

SERIOUS apprehensions have been excited at Nantwich in

Cheshire by the repeated landslips which have occurred there. For several winters in succession large surfaces of ground have fallen in, it is supposed on account of the withdrawal of the salt from the salt-mines. The slip which occurred this winter is on the same spot where similar occurrences happened twelve months, two, and four years ago. The pit is about 300 yards in circumference, and about 100 feet deep, and the sides are almost perpendicular. It is feared that if these subsidences continue the town itself will be threatened, and the attention of the Government has been called to them.

MR. W. LAIRD CLOWES, in a letter to a contemporary dated The Cottage, Pinner, Monday, Jan. 8, writes:—"To-night, between 8.15 and 8.30, I noticed three beautifully luminous atmospheric phenomena on the northern horizon. They all took the form of an arc of fire of between 8° and 10° in height, the first two happening within a minute of one another, and the last about eleven minutes after the second. There were a slight breeze and light clouds at the time." This was most probably an aurora borealis, but we have not seen any other account of it.

THE Trinity Board have established an electric light at the South Foreland lighthouse, which is situated between Dover and Deal. It was formally opened on New Year's Day by Sir Frederick Arrow, the Deputy-Master of the Trinity Board, in the place of Prince Arthur, who was prevented from being present. This lighthouse establishes a triangle of electric lights, the other two being at Dungeness and Cape Grinsez.

THE accounts furnished by the *Boston Advertiser* from the captains and crews of the vessels of the whaling fleet lately destroyed or ice-bound in the Arctic Ocean concur in describing the presence of peculiar meteorological phenomena during the past season. The prevailing summer wind on the north-west coast of Alaska is from the north, and this works the ice off from the land and disperses it, while the north-westerly winds close it up on the shore. As the ice moves off, the ships generally work up by the land, and in that situation find whales in plenty. By the end of the season, when north-westerly winds are prevalent, the ice becomes so broken up and melted that it has ceased to be an element of danger, and the vessels are compelled to retire to the northward by heavy ice drifting along the coast from the north, and not from a threatened closing in upon the land. But this season the easterly winds were not so strong and constant as usual, and the ice that had gone off from shore returned in a heavy pack, so that it was impossible to get a ship through, or even to hold against it at anchor. The heavy ice-fields are all composed of fresh-water berg-ice, not floe-ice of salt-water. The bergs are not of the immense proportions seen in Greenland seas, but are solid enough to be equally dangerous, many masses being so heavy as to ground in ten fathoms of water.

ON Nov. 15 the town of Oran, the second city in the province of Salta, was destroyed by a series of earthquakes lasting nine hours. Very little life was lost, the first shocks being light. The inhabitants had time to flee to the open camp of Monte Video.

SCIENTIFIC INTELLIGENCE FROM AMERICA*

ADVICES from Lieutenant G. M. Wheeler, United States Engineers, whose movements during the past year we have had frequent occasion to chronicle, announce his arrival at Tucson about Dec. 4, with the men and animals nearly exhausted. The trip from Prescott to Camp Apache had been very severe, on account of the snow and high winds on the Colorado plateau. During their exploration one party had been sent to the San

Francisco mountains, and made the ascent of the principal peak. These mountains consist of three prominences, grouping in the form of a crater, the north-eastern rim being wanting. The principal peak was occupied as a topographical, barometrical, and photographic station. It is believed to be nearly 1,000 feet higher than the peak usually ascended; and Lieutenant Wheeler was of the opinion that his party was the first to occupy its summit. This, however, was a mistake, as Dr. Edward Palmer, of the Smithsonian Institution, made the ascent in 1870, and obtained a number of new species of plants and insects.—A document which has been for some years in preparation, and toward which much expectation has been directed by agriculturists, has just appeared from the Government press, namely, the Report of the Commissioner of Agriculture upon the Diseases of Cattle in the United States. About the middle of June, 1868, a disease broke out at Cairo, Illinois, among a number of Texas cattle, known as the Spanish fever, or the Texas cattle disease. In consequence of the rapid extension of this disease, very serious alarm was excited, and the services of Prof. John Gamgee, a distinguished English veterinarian, then in the United States, were secured by General Capron, the Commissioner of Agriculture, for the purpose of instituting a careful inquiry as to its cause, course, and methods of treatment. The Professor immediately visited the infected districts in Illinois, and in the spring of 1869 examined that part of Texas on or near the Gulf coast, where the transportation of the native cattle begins. In this last journey he was accompanied by Prof. Ravenel, of South Carolina, a specialist among the fungi, and whose particular object was to determine what part such plants played in the infection. Dr. J. S. Billings and Dr. Curtis, of the army, were also associated in the inquiry, having special reference to the microscopic investigations. A second investigation by Prof. Gamgee, under the authority of the Commissioner of Agriculture, had reference to the subject of pleuro-pneumonia, in the course of which numerous microscopic observations were made by Dr. Woodward, of the Army Medical Museum. Full reports on these various subjects made by the different gentlemen are embodied in the volume referred to, which appears in quarto form, with numerous well-executed plates in chromo-lithography. It is also accompanied by a report by Mr. Dodge, the statistician of the Agricultural department, upon the history of this Texas cattle disease, also known as splenic fever, in which the devastations of this peculiar native malady are traced back into the eighteenth century. This report was considered by General Capron as simply preliminary, and further investigations are indicated as important. Among those especially mentioned are inquiries as to the best mode of arresting the contagion, and the proper way of transportation of the cattle northward. He thinks that a general law of the United States, in the interest of public health, of an enlightened humanity, and of the cattle trade, should regulate this traffic, not only throughout the Gulf States, but on the great routes throughout the country.—A valuable document lately issued by the Surgeon-General's Office at Washington, prepared by Dr. G. A. Otis, consists of a report of surgical cases treated in the army of the United States from 1865 to 1871, covering almost every possible variety of injury, whether by gun-shot wounds, lacerations, fractures, dislocations, amputations, &c. The report, which is a quarto of nearly 300 pages, is illustrated in the same excellent style as its predecessors, and the woodcuts are especially worthy of all praise.—Bills have been introduced both in the Senate and House of Representatives providing for the reservation of that portion of the region about the Yellow Stone Lake, in which the wonderful geysers and hot springs occur, to which we have repeatedly called the attention of our readers. The thorough exploration of that country made during the past season by Dr. Hayden has enabled him to define the limits within which these natural features occur, and the bill is based upon a plan prepared under his direction. The area proposed to be preserved is about sixty-five miles in length by fifty-five in width, and it is suggested that the reservation be placed under the direction of the Secretary of the Interior, who is to be empowered to take such steps as may be required to protect the natural curiosities from injury or destruction. It is highly important that this should become a law at the present session, as the glowing accounts given by Dr. Hayden will cause a great many persons to visit the country during the coming year, and with the natural iconoclasm of the Anglo-Saxon race, there is great danger that the wonderful water basins and formations of sulphur and of calcareous and siliceous rocks will be knocked to pieces for the purpose of securing mementoes of a visit.

* Communicated by the Scientific Editor of *Harper's Weekly*.

THE LAWS OF ORGANIC DEVELOPMENT*

THE discussion of this subject divides itself into two parts, viz.: a consideration of the proof that evolution of organic types, or descent with modification, has taken place; and, secondly, the investigation of the laws in accordance with which this development has progressed.

I.—On the Proof for Evolution.

There are two modes of demonstration, both depending on direct observation. One of these has been successfully presented by Darwin. He has observed the origin of varieties in animals and plants, either in the domesticated or wild states, and has shown, what had been known to many, the lack of distinction in the grades of difference which separate varieties and species. But he has also pointed out that species (such, so far as distinctness goes) have been derived from other species among domesticated animals, and he infers by induction that other species, whose origin has not been observed, have also descended from common parents. So far I believe his induction to be justified: but when from this basis evolution of divisions defined by important structural characters, as genera, orders, classes, &c., is inferred, I believe that we do not know enough of the uniformity of nature's processes in the premises to enable us so regard this kind of proof as conclusive.

I therefore appeal to another mode of proving it, and one which covers the case of all the more really structural features of animals and plants.

It is well known that in both kingdoms, in a general way, the young stages of the more perfect types are represented or imitated with more or less exactitude by the adults of inferior ones. But a true identity of these adults with the various stages of the higher has, comparatively, rarely been observed. Let such a case be supposed.

In *A* we have four species whose growth attains a given point, a certain number of stages having been passed prior to its termination or maturity. In *B* we have another series of four (the numbering a matter of no importance), which, during the period of growth, cannot be distinguished by any common, *i.e.*, generic character, from the individuals of group *A*, but whose growth has only attained to a point short of that reached by those of group *A* at maturity. Here we have a parallelism, but no true evidence of descent. But if we now find a set of individuals belonging to one species, and therefore held to have had a common origin or parentage (or still better the individuals of a single brood), which present differences among themselves of the character in question, we have gained a point. We know in this case that the individuals *a*, have attained to the completeness of character presented by group *A*, while others, *b*, of the same parentage, have only attained to the structure of those of group *B*. It is perfectly obvious that the individuals of the first part of the family have grown further, and, therefore, in one sense faster, than those of group *b*. If the parents were like the individuals of the more completely grown, the offspring which did not attain that completeness may be said to have been retarded in their development. If, on the other hand, the parents were like those less fully grown, then the offspring which have added something have been accelerated in their development.

I claim that a consideration of the uniformity of nature's processes, or inductive reasoning, requires me (however it may affect the minds of others) to believe that the groups of species whose individuals I have never found to vary, but which differ in the same point as those in which I have observed the above variations, are also derived from common parents, and the more advanced have been accelerated or the less advanced retarded, as the case may have been with regard to the parents.

This is not an imaginary case, but a true representation of many which have come under my observation. The developmental resemblances mentioned are universal in the animal and probably in the vegetable kingdoms, approaching the exactitude above depicted in proportion to the near structural similarity of the species considered.

II.—On the Laws of Evolution.

Wallace and Darwin have propounded as the cause of modification in descent their law of natural selection. This law has been epitomised by Spencer as "the preservation of the fittest." This neat expression no doubt covers the case, but it leaves the

origin of the fittest entirely untouched. Darwin assumes a "tendency to variation" in nature, and it is plainly necessary to do this in order that materials for the exercise of a selection should exist. Darwin and Wallace's law is, then, only restrictive, directive, conservative, or destructive of something already created. Let us, then, seek for the originative laws by which these subjects are furnished—in other words, for the causes of the origin of the fittest.

The origin of new structures which distinguish one generation from those which have preceded it, I have stated to take place under the law of acceleration. As growth (creation) of parts usually ceases with maturity, it is entirely plain that the process of acceleration is limited to the period of infancy and youth in all animals. It is also plain that the question of growth is one of nutrition, or of the construction of organs and tissues out of protoplasm.

The construction of the animal types is restricted to two kinds of increase—the addition of identical segments and the addition of identical cells. The first is probably to be referred to the last, but the laws which give rise to it cannot be here explained. Certain it is that segmentation is not only produced by addition of identical parts, but also by subdivision of a homogeneous part. In reducing the vertebrate or most complex animal to its simplest expression, we find that all its specialised parts are but modifications of the segment, either simply or as sub-segments of compound but identical segments. Gegenbaur has pointed out that the most complex limb with hand or foot is constructed, first, of a single longitudinal series of identical segments, from each of which a similar segment diverges, the whole forming parallel series, not only in the oblique transverse, but generally in the longitudinal sense. Thus the limb of the Lepidosiren represents the simple type, that of the Ichthyosaurus a first modification. In the latter the first segment only (femur or humerus) is specialised, the other pieces being undistinguishable. In the Plesiosaurian paddle the separate parts are distinguished; the ulna and radius well marked, the carpal pieces hexagonal, the phalanges well marked, &c.

As regards the whole skeleton, the same position may be safely assumed. Though Huxley may reject Owen's theory of the vertebrate character of the segments of the cranium, because they are so very different from the segments in other parts of the column, the question rests entirely on the definition of a vertebra. If a vertebra be a segment of the skeleton, of course the skull is composed of vertebrae; if not, then the cranium may be said to be formed of "sclerotomes," or some other name may be used. Certain it is, however, that the parts of the segments of the cranium may be now more or less completely parallelised or homologised with each other, and that as we descend the scale of vertebrate animals, the resemblance of these segments to vertebrae increases, and the constituent segments of each become more similar. In the types where the greatest resemblance is seen, segmentation of either is incomplete, for they retain the original cartilaginous basis. Other animals which present cavities or parts of a solid support are still more easily reduced to a simple basis of segments, arranged either longitudinally (worm) or centrifugally (star-fish, &c.).

Each segment—and this term includes not only the parts of a complex whole, but parts always subdivided, as the jaw of a whale or the sac-body of a mollusc—is constructed, as is well known, by cell-division. In the growing fetus the first cell divides its nucleus and then its whole outline, and this process repeated millions of times produces, according to the cell theory, all the tissues of the animal organism or their bases from first to last. That the ultimate or histological elements of all organs are produced originally by repetitive growth of simple, nucleated cells with various modifications of exactitude of repetition in the more complex, is taught by the cell theory. The formation of some of the tissues is as follows:—

First Change.—Formation of simple nucleated cells from homogeneous protoplasm or the cytoblastema.

Second.—Formation of new cells by division of body and nucleus of the old.

Third.—Formation of tissues by accumulation of cells with or without addition of intercellular cytoblastema.

A. In connective tissue by slight alteration of cells and addition of cytoblastema.

B. In blood, by addition of fluid cytoblastema (fibrin) to free cells (lymph cor-cules), which in higher animals (vertebrates) develop into blood-corpuscles by loss of membrane, and by cell development of muscles.

* Abstract of paper by Prof. E. D. Cope, read at the Indianapolis meeting of the American Association for the Advancement of Science; reprinted from the *American Naturalist*.

C. In muscles by simple confluence of cells, end to end, and mingling of contents (Kölliker).

D. Of cartilage by formation of cells in cytotblast which break up, their contents being added to cytotblast; this occurring several times, the result being an extensive cytotblast with few and small cells (Vogt). The process is here an attempt at development with only partial success, the result being a tissue of small vitality.

Even in repair-nutrition recourse is had to the nucleated cell. For Cohnheim first shows that if the corner of a frog's eye be scarified, repair is immediately set on foot by the transportation thither of white or lymph or nucleated corpuscles from the neighbouring lymph heart. This he ascertained by introducing aniline dye into the latter. Repeated experiments have shown that this is the history in great part of the construction of new tissue in the adult man.

Now, it is well known that the circulating fluid of the fœtus contains for a period only these nucleated cells as corpuscles, and that the lower vertebrates have a greater proportion of these corpuscles than the higher, whence probably the greater facility for repair or reconstruction of lost limbs or parts enjoyed by them. The invertebrates possess only nucleated blood corpuscles.

What is the relation of cell division to the forces of nature, and to which of them as a cause is it to be referred, if to any? The animal organism transfers the chemistry of the food (protoplasm) to correlated amounts of heat, motion, electricity, light (phosphorescence), and nerve force. But cell division is an affection of protoplasm distinct from any of these. Addition to homogeneous lumps or parts of protoplasm (as in that lowest animal, *Protanaba* of Haeckel) can be an exhibition of mere molecular force, or addition as is seen in the crystal, but cell division is certainly something distinct. It looks to me like an exhibition of another force, and though this is still an open question, it may be called for the present *growth force*. It is correlated to the other forces, for its exhibitions cease unless the protoplasm exhibiting it be fed. It is potential in the protoplasm of both protoplasmic animal mass and protoplasmic food, and becomes energetic on the union of the two. So long as cell-division continues it is energetic; when cells burst and discharge the contained cytoblastema, as in the formation of cartilage, it becomes again potential.

The size of a part is then dependent on the amount of cell division or growth force, which has given it origin, and the number of segments is due to the same cause. The whole question, then, of the creation of animal and vegetable types is reduced to one of the amount and location of growth force.

Before discussing the influences which have increased and located growth force, it will be necessary to point out the mode in which these influences must necessarily have affected growth. Acceleration is only possible during the period of growth in animals, and during that time most of them are removed from the influence of physical or biological causes either through their hidden lives or incapacity for the energetic performance of life functions. These influences must, then, have operated on the parents, been rendered potential in their reproductive cells, and become energetic in the growing fœtus of the next generation. However little we may understand this mysterious process, it is nevertheless a fact. Says Murphy, "There is no act which may not become habitual, and there is no habit which may not be inherited." Materialised, this may be rendered—there is no act which does not direct growth force, and therefore there is no determination of growth force which may not become habitual; there is, then, no habitual determination of growth force which may not be inherited; and of course in a growing fœtus becomes at once energetic in the production of new structure in the direction inherited, which is acceleration.

III.—The Influences Directing Growth Force.

Up to this point we have followed paths more or less distinctly traced in the field of nature. The positions taken appear to me either to have been demonstrated or to have a great balance of probability in their favour. In the closing part of these remarks I shall indulge in more of hypothesis than heretofore.

What are the influences locating growth force? First, physical and chemical causes; second, use; third, effort. I leave the first, as not especially prominent in the economy of type growth among animals, and confine myself to the two following. The effects of use are well known. We cannot use a muscle without increasing its bulk; we cannot use the teeth in mastication without inducing a renewed deposit of dentine within the pulp-

cavity to meet the encroachments of attrition. The hands of the labourer are always larger than those of men of other pursuits. Pathology furnishes us with a host of hypertrophies, exostoses, &c., produced by excessive use, or necessity for increased means of performing excessive work. The tendency, then, induced by use by the parent is to add segments or cells to the organ used. Use thus determines the locality of new repetitions of parts already existing, and determines an increase of growth force at the same time, by the increase of food always accompanying increase of work done, in every animal.

But supposing there be no part or organ to use. Such must have been the condition of every animal prior to the appearance of an additional digit or limb or other useful element. It appears to me that the cause of the determination of growth force is not merely the irritation of the part or organ used by contact with the objects of its use. This would seem to be the remote cause of the deposit of dentine used in the tooth, in the thickening epidermis of the hand of the labourer, in the wandering of the lymph-cell to the scarified cornea of the frog in Cohnheim's experiment. You cannot rub the sclerotic of the eye without producing an expansion of the capillary arteries and corresponding increase in the amount of nutritive fluid. But the case may be different in the muscles and other organs (as the pigment cells of reptiles and fishes) which are under the control of the volition of the animal. Here, and in many other instances which might be cited, it cannot be asserted that the nutrition of use is not under the direct control of the will through the mediation of nerve force. Therefore I am disposed to believe that growth force may be, by the volition of the animal, as readily determined to a locality where an executive organ does not exist, as to the first segment or cell of such an organ already commenced, and that therefore effort is in the order of time the first factor in acceleration.

Effort and use have, however, very various stimuli to their exertion.

Use of a part by an animal is either compulsory or optional. In either case the use may be followed by an increase of nutrition under the influence of reflex force or of direct volition.

A compulsory use would naturally occur in new situations which take place apart from the control of the animal, where no alternatives are presented. Such a case would arise in a submergence of land where land animals might be imprisoned on an island or in swamps surrounded by water, and compelled to assume a more or less aquatic life. Another case which has also probably often occurred, would be when the enemies of a species might so increase as to compel a large number of the latter to combat who would previously have escaped it.

In these cases the structure produced would be necessarily adaptive. But the effect would be most frequently to destroy or injure the animals (retard them) thus brought into new situations and compelled to an additional struggle for existence, as has, no doubt, been the case in geologic history. Preservation, with modifications, would only ensue where the changes should be introduced very gradually. This mode is always a consequence of the optional use. The cases here included are those where choice selects from several alternatives, thus exercising its influence on structure. Choice will be influenced by the emotions, the imagination, and by intelligence.

As examples of intelligent selection the modified organisms of the varieties of bees and ants must be regarded as striking examples of its exercise. Had all in the hive or hill been modified alike, as soldiers, queens, &c., the origin of the structures might have been thought to be compulsory; but varied and adapted as the different forms are to the wants of a community, the influence of intelligence is too obvious to be denied. The structural results are obtained in this case by a shorter road than by inheritance.

The selection of food offers an opportunity for the exercise of intelligence, and the adoption of means for obtaining it still greater ones. It is here that intelligent selection proves its supremacy as a guide of use, and consequently of structure, to all the other agencies here proposed. The preference for vegetable or for animal food determined by the choice of individual animals among the omnivores, which were, no doubt, according to the paleontological record the predecessors of our herbivores, and perhaps of carnivores also, must have determined their course of life, and thus of all their parts into those totally distinct directions. The choice of food under ground, on the ground, or in the trees would necessarily direct the uses of organs in those directions respectively.

Intelligence is a conservative principle, and always will direct effort and use into lines which will be beneficial to its possessor. Thus we have the source of the fittest—i.e., addition of parts by increase and location of growth force directed by the will—the will being under the influence of various kinds of compulsory choice in the lower, and intelligent option among higher animals. Thus intelligent choice may be regarded as the originator of the fittest, while natural selection is the tribunal to which all the results of accelerated growth are submitted. This preserves or destroys them, and determines the new points of departure on which accelerated growth shall build.

Acceleration under the influence of effort accounts for the existence of rudimental characters. Many other characters will follow at a distance, the modifications proceeding in accordance with the laws here proposed, and retardation is accounted for by complementary or absolute loss of growth force.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 18.—“Investigations of the Currents in the Strait of Gibraltar, made in August 1871,” by Captain G. S. Nares, R.N., of H.M.S. *Shearwater*, under instructions from Admiral Richards, F.R.S., Hydrographer of the Admiralty.

Geological Society, Jan. 10.—Mr. Joseph Prestwich, F.R.S., president, in the chair. “On *Cyclostigma*, *Lepidodendron*, and *Knorria* from Kiltorkan.” By Prof. Oswald Heer. In this paper the author indicated the characters of certain fossils from the yellow sandstone of the South of Ireland, referred by him to the above genera, and mentioned in his paper “On the Carboniferous Flora of Bear Island,” read before the Society on November 9, 1850 (see Q. J. G. S. vol. xxvii. p. 1). He distinguished as species *Cyclostigma kiltorkense*, Haught., *C. minutum* (Haught.), *Knorria acicularis*, Göpp. var. *Baillyana*, and *Lepidodendron Veltheimianum*, Sternb.—Mr. Carruthers was glad that he had made the observations which he did on Prof. Heer's former paper, as it had caused the Professor to give the reasons on which his opinions were based. He was doubtful whether the success which had attended Prof. Heer's determination of species from leaves justified the application of the same principles to mere stems. He could not accept the difference in size or distance of leaf-scars as a criterion of species, inasmuch as they were merely the result of the difference in the age and size of the parts of the plants on which they were observed. Even Prof. Heer himself had united together specimens presenting greater differences in this respect than those which he distinguished. He considered *Cyclostigma kiltorkense*, *C. minutum*, and *Lepidodendron Veltheimianum* to be founded on different parts of one species. In the Kiltorkan fossils the outer surface of the original stems was often broken up into small fragments, the phyllotaxy on which proved them to be portions of large stems, and not entire branches. As to *Knorria*, it was certainly the interior cast of the stem of *Lepidodendron*, with casts of the channels through which the vascular bundles passed with some cellular tissue to the leaves; and the specimen figured showed that it belonged to a branch similar to that represented as *C. minutum*. He considered that the four supposed species belonging to three genera were only different forms of the same plant.—“Notes on the Geology of the Plain of Morocco, and the Great Atlas.” By Mr. George Maw. The author described first the characters presented by the coast of Morocco, and then the phenomena observed by him in his progress into the interior of the country and in the Atlas Chain. The oldest rocks observed were ranges of metamorphic rocks bounding the plain of Morocco, interbedded porphyries and the porphyritic tuffs forming the backbone of the Atlas Chain, and the Mica-schists of Djeb Tezah in the Atlas. At many points in the lateral valleys of the Atlas almost vertical grey shales were crossed; the age of these was unknown. Above these comes a Red Sandstone and Limestone series, believed to be of Cretaceous age, and beds possibly of Miocene age, which occupied the valleys of the Atlas and covered the plain of Morocco, where vestiges of them remain in the form of tabular hills. The probable age of these beds was determined on the evidence of fossils. The author noticed the sequence of denuding and eruptive phenomena by which the arrangement and distribution of these rocks has been modified, and described the more recent changes resulting in the formation of enormous boulder-beds flanking the northern escarpment of the Atlas plateau, and of great moraines at the heads of the valleys of the

Atlas, both of which he ascribed to glacial action. An elevation of the coast line of at least seventy feet was indicated by raised beaches of concrete sand at Mogador and elsewhere, and the author considered that a slight subsidence of the coast was now taking place. The surface of the plain of Morocco was described as covered with a tuffaceous crust, probably due to the drawing up of water to the surface from the subjacent calcareous strata and the deposition from it of laminated carbonate of lime. Mr. Ball, as an Alpine traveller who had also visited the Atlas in company with Dr. Hooker and Mr. Maw, offered a few remarks. The plain of Morocco was not, in his opinion, a level, but an inclined plane, rising gradually in height up to the foot of the mountain, so that the base of the boulder ridges was at some height above the level of the plain near Morocco. He did not think that the boulder deposits could be safely attributed to glaciers, but thought rather that they had been carried into and deposited in a shallow sea. He thought also that Mr. Maw had somewhat over-estimated the thickness of some of the boulder deposits; and though there was one instance of an undoubted moraine in one of the higher valleys of the Atlas, yet he could not agree in the view that the glaciation of the Atlas was general. He could not accept such a great thickness of beds as that represented by the vertical shales in Mr. Maw's section. Prof. Ramsay was pleased that the author, though giving so many interesting details, had not assigned any definite age to many of the beds. He agreed with him as to the cause assigned for the great tuffaceous coating of the country. He had already assigned the same cause for the existence of certain saline beds, and would attribute the existence of the great coating of gypsum at slight depth below the surface of the Sahara to the same cause. As to the existence of moraines, he was not surprised to find them in the Atlas, as they were already known in the mountains of Granada. As to the escarpments, it was now well known that, as a rule, they assumed a direction approximately at right angles to the dip of the strata; and he felt inclined to consider that the bulk of the mounds at the foot of the escarpment of the Atlas were rather the remains of a long series of landslips from the face of the cliffs than to an accumulation of moraine matter. Mr. D. Forbes commented on the similarity of the rocks to those of the Andes in South America. In the Andes the porphyritic tuffs appeared to belong to the Oolitic age; and the igneous rocks associated with them were of the same date. He thought that, so far as the author's observations had gone, the structure of the Atlas was much the same as that of the Andes. Mr. W. W. Smyth mentioned that in the district to the east of the Sierra Nevada, in the south part of Spain, where there was great summer heat, and also heavy occasional rainfall, the same tuffaceous coating as that observed in Morocco was to be found. He had been led to much the same conclusion as to its origin as that arrived at by Mr. Maw. The upper part was frequently brecciated, and the fragments re-cemented by carbonate of lime. Mr. Seeley, though accepting Mr. Etheridge's determination as to the Cretaceous age of the fossils if found in England, could not accept it as conclusive in the case of fossils from Morocco. The genus *Exogyra*, for instance, which ranges through the Secondary to existing seas, might well belong to some other age; and even the fossils presumably Miocene might, after all, date from some other period. Mr. Maw, in reply, stated that he agreed with Mr. Ball as to the rise in the Moroccan plain as it approached the Atlas, having taken it in one direction at 400 feet in 25 miles. He pointed out the resemblance between the moraines in the valley of the Rhone and those which he regarded as such on the flanks of the Atlas. As a proof of their consisting of transported blocks, he mentioned the fact that the Red Sandstone rock of which they were composed did not occur in the adjacent escarpments, but was not to be found within seven or eight miles. There was, moreover, a mixture of different materials in the mounds.

Linnean Society, January 18.—Mr. Bentham, president, in the chair. “On the Anatomy of *Limulus polyphemus*,” by Prof. Owen (continued). The author resumed and concluded the reading of this memoir. The nervous system of *Limulus* appeared to have occupied most attention, and was described in detail. From the fore part of the oesophageal ring, answering to the brain, were sent off the “ocellar,” “ocular,” “antennular,” and “antennal” nerves; the latter supplying the second pair of articulate limbs—the homologues of the “external antennæ” of higher Crustacea. From the post- or sub-oesophageal part of the ring, proceeded large nerves to the four succeeding pairs of limbs; and also smaller nerves, having distinct origins,

to the chilaria and to the opercular plate-limbs. The neural axis then continues, as a pair of coalesced chords, to the middle of the thoracetrone, developing five ganglions supplying the five gill-limbs. Beyond the fifth ganglion the chords separate; each forms a loop resembling a ganglion, beyond which each chord penetrates the base of the "pleon." To this it supplies five dorsal and five ventral nerves before being continued and resolved into a plexus toward the end of the tail and spine. The author remarked that, as the nervous system preceded the tegumentary in the order of development, it might thus manifest evidences of the more generalised segmental type of the pleon, more plainly than had been noticed in the formation of the chitinous walls of that division of the body, in the embryo, in which it first budded forth as a ninth segment of the thoracetrone. Details of the organs of the senses, of the digestive, circulatory, respiratory, and generative systems were then given, and illustrated, like the nervous system, by minutely-finished drawings. The heart was elongate, vasiform, included in a pericardial-like sinus; besides an anterior and posterior aortic trunk, there were seven pairs of lateral primary branches. The arteries soon lose their tubular form, and, as they expand, lose likewise much of their fibrous walls, and seem reduced to delicate membranous sinuses which follow the shapes of the parts or interstices along which the blood meanders as it returns by the venous sinuses to the general pericardial one. The most remarkable of the arterial prolongations are those which the author had previously described in his "Lectures on Invertebrata" (Svo ed., 1855, p. 310) as expanding upon, and seeming to form the neurilemma of, the central axis and branches of the nervous system; so that injection of the anterior aorta coats the neurine and demonstrates a great part of the nervous system by its colour. (A drawing showing this effect of fine red injection was exhibited.) Finally the author cited the chief results of the observations of Lockyer, Packard, and Dohrn on the development of the king-crab. There was neither a nauplius stage nor a trilobite stage. A superficial resemblance to trilobites is shown by the absence of the pleon in the embryo king-crab; but the very fact of the late appearance of this terminal division was decisive against any real representative resemblance of the embryo *Limulus* to the trilobites; on the acceptance, at least, of Barrande's observations of the successive and later appearance of the segments of the "thoracetrone" in the space between the head ("cephaletron") and "pygidium" (pleon and tail-spine) of the embryos of *Sao*, *Agnostus*, and *Trinucleus*. The author here recalled attention to Newport's observations of the like development of successive segments, anterior to the caudal one, in *Iulide*, and remarked that with other facts noted in the anatomical sections, especially the fusion of the pair of cephalic ganglia, and the short and thick crura connecting these with the subesophageal mass, giving the condition of that part of the nervous system in *Scorpio* and *Iulus*, *Limulus* manifested in an instructive and interesting way the more "generalised type" of articulate structure, in which arachnid and myriapod characters were associated with crustacean ones. But, in the development of *Limulus*, the pleon, pygidium, or tail-spine was the last to appear, and, at its first budding, looked like a ninth segment of the thoracetrone. Packard speaks of indications, transitory indeed, of segmentation of the crust; and such indications, as the author had shown in the anatomy of *Limulus*, were more strongly and lastingly given by the nervous system. The tail-spine belongs to the series of body-segments, and is no mere appendage to the dorsal arc of such. After formation of the attractive and repellent forces have produced in the germ-masses the phenomena of segmentation and vegetative repetition, as manifested in the similar and parallel heaps of granules, like bricks for the building, the inherited influences overrule the polar ones, and operate in differentiating and adaptive lines, speedily showing the embryo *Limulus*, which like that of *Astacus fluviatilis*, *Palaeonotus asperus*, *Crangon maculosus*, *Eriphia spinifrons*, and one may add, all Cephalopods, takes its own course to the full manifestation of its specific characters, agreeably with the nature originally impressed on the germ. There was no divergence to a larval form with a term of active life as such; there was no metamorphosis, either "naupliar" or "trilobitic." Some objected to the king-crabs being called Crustacea; there was more ground, the author thought, for objecting to call them Arachnida or Myriapoda. Characters common to *Limulus* with their allied extinct gill-bearing, well-limbed Articulata, have not a class-value. The author could not, at least, raise the Merostomes to an equivalency with, and run them parallel to and alongside of, the rest of the

branchiate Condylapods. A class, after all, was an artificial group, a help to the classifier. One may call *Limulus* a Crustacean and yet discern in its anatomy the evidence of its more "generalised structure" than in Malacostraca; its type preceded that of either macrurous or brachyurous Crustacea, and indicates characters subsequently appropriated by and intensified in the air-breathing members of the Aptero Insecta of Linnaeus. As compared with its longer-bodied and many-jointed predecessors, *Limulus* itself shows a concentrative specialisation; but vegetative repetition still reigns in the limb-series. "Inner antennules," "outer antennae," "mandibles," "maxillae," "maxillipeds," "legs," all work together by their basal joints in subservency to mastication, and all end in pincers. As compared with modern crabs no structure was more striking and significant than the resistance, so to speak, of the heart in *Limulus* to the concentrative tendencies; it is still the "dorsal vessel," though the body-part containing it has the breadth and shortness of the crab's carapace, in which the heart is shaped to match. In both the neural axis supplying the cephalic limbs is annular, but in modern crabs the subesophageal part is defined by distance and concomitantly long and slender from the super-esophageal or cerebral part. This differentiation had not taken place in *Bellinurus*, *Neolimulus*, *Prestwichia*, and other palaeozoic predecessors of *Brachyura*, whose organisation we have to thank their long-lived, lingering representative genus for enabling us to peer into. That such glimpses, with concomitant tracing of the development of the individual *Limulus*, afford us some ground, and that the like work, with persevering quest of its palaeozoic fossil allies, may afford more, for guessing at the ways in which a pre-ordained plan of derivation by congenital departures from parental form has operated, in originating the various deviations from a common primitive articulate type, is an encouraging faith. That the old ocean should have given the chance conditions of origin of crustacean sub-classes, orders, genera, species, by natural selection, was not conceivable by the author, who, nevertheless, held the conviction that all forms and grades of Articulata were due to "secondary cause or law," as strongly as when he expressed the same conclusion in regard to the Vertebrata, and termed it "the deep and pregnant principle" evolved in the researches on the general homologies and archetype of their skeletons.

Mathematical Society, January 11.—Mr. W. Spottiswoode, F.R.S., president, and subsequently Prof. Cayley, V.P., in the chair. Major E. Close, R.A., was admitted into the society. Prof. Cayley gave an account of his paper "On the Surfaces the loci of the Vertices of Cones which satisfy six conditions."—Mr. J. W. L. Glaisher stated and illustrated the principal points in his communication "On the Constants which occur in certain summations by Bernoulli's Series."—Mr. W. B. Davis read a paper describing the methods he had used in the construction of tables of divisors, and exhibited tables of factors of numbers consisting of nine and twelve figures. A brief discussion ensued on the subject of this communication.—Mr. Roberts explained some of the results which he submitted to the society in his paper "On the parallel surface of Conicoids and Conics," and illustrated the same by means of a model and drawings of sections of one of the surfaces.

Zoological Society, January 16.—Prof. Newton, F.R.S., vice-president, in the chair.—The Secretary read a report on the additions that had been made to the Society's collection during the month of December, 1871, amongst which was particularly mentioned a young Prince Alfred's Deer (*Cervus alfredi*), born in the Gardens.—A letter was read from Prof. Owen, F.R.S., communicating some particulars received from Dr. Julius Haast, of Christchurch, New Zealand, respecting the finding of the remains of *Aptornis* in the Glenmark Swamp, New Zealand.—Mr. H. E. Dresser exhibited and made remarks on specimens of the eggs of *Reguloides superciliosus* and *Reguloides occipitalis*, collected by Mr. W. E. Brooks in Cashmere.—A communication was read from Dr. G. Hartlaub and Dr. O. Finsch, giving an account of a collection of birds from the Pelew and Mackenzie Islands in the Pacific, to which was added a complete synopsis of the ornithology of this portion of the Caroline group.—A communication was received from Mr. A. Sanders, containing a complete description of the Myology of *Liopelis berti*.—Mr. A. G. Butler communicated a synonymic list of the species formerly included in the genus *Picris*, with references to all others described since the subdivisions of that genus by recent authors.—A communication was read from Mr. John Brazier, of Sydney, N.S.W., giving a list of the *Cypraea* met with on the coast of New

South Wales.—A paper by Mr. A. Anderson was read containing the second portion of his notes on the Raptorial Birds of India.

Chemical Society, January 18.—Dr. Frankland, F.R.S., president, in the chair.—At this meeting Dr. Odling exhibited some very fine specimens of rare metals and their compounds, which had been lent to him by Dr. Richter and Dr. Theodor Schuchardt. Among these was a bar, weighing about seven ounces, of metallic indium; an element discovered a few years ago by Richter, in conjunction with Reich; also some metallic rubidium.—Dr. David Howard then read an interesting paper "On quinine and cinchonine and their salts." These alkaloïds are prepared artificially, from quinine and cinchonine respectively, by the action of heat on their salts, and are isomeric with them. Quinine occurs along with the two last-mentioned alkaloïds in cinchona bark, being apparently the one which is first formed during the growth of the cinchona plant.

PARIS

Academy of Sciences, January 15.—A note by M. M. Lévy on a property of the focals of surfaces, was presented by M. Bertrand, in which the author puts forward the proposition that any surface and its focal intersect each other at right angles.—A note from M. Catalan, on General Didion's communication concerning the relation of the circumference to the diameter, was read, in which the authorship of similar formulæ is ascribed to Euler.—M. II. Resal communicated a memoir containing equations of the vibratory movement of a circular plate, and M. Serret a note by M. E. Clotti on the employment of vibrating elastic plates for the realisation of a propeller, in connection with a recent communication from M. de Tastes.—A memoir on the measurement of very high temperatures, and on the temperature of the sun, by M. H. Sainte-Claire Deville, was read. The author maintained that the temperatures which may be produced and measured in the laboratory are not greatly exceeded in nature, and that the temperature of the sun is not far from 2,500–2,800° C. (= 4,532–5,072° F.). M. Delaunay read a note on the secular variations of the mean movements of the perigee and node of the moon.—M. Faye presented a note upon the investigations of Dr. Heis on meteors, which are confirmatory of M. Faye's previous communication as to the different centres of radiation observed in November last.—A letter was read from M. Janssen on the principal consequences which may be drawn at present from his observations of the eclipse of December last. (A translation of this letter will be found in another column.)—M. P. Guyot forwarded a note on a meteor observed at Nancy on the 20th of December last at 10h. 28m. A.M. This meteor passed from Cassiopeia through Perseus towards the Pleiades, near which it exploded, with a bright green light.—M. E. Becquerel presented a report on various memoirs by M. W. de Fonville regarding observations to be effected during balloon ascents. M. E. Becquerel also presented a note by M. T. Sidot on the electrification by friction of metals in sulphide of carbon, and on the decomposition of that body by light. The author finds that certain metals, especially silver, aluminium, and iron, become electrified, and produce sparks when strongly agitated with pure sulphide of carbon, and that the latter, when exposed to the light of the sun, is decomposed, producing a gas and a solid flocculent matter. The same gentleman also communicated a joint note by MM. F. Lucas and A. Cazin containing an account of some experimental researches upon the duration of the electric spark.—Notes by M. Lion and M. Diamilla Müller on the action of ecliptical conjunctions upon the elements of terrestrial magnetism were read. According to the former considerable perturbations were observed at Alençon during the eclipse of the 11th December last.—M. P. Tarry presented a further note on the movement of recoil of cyclones in equatorial regions.—In a paper on the combustion of carbon by oxygen, M. Dumas showed, in opposition to M. Dubrunfaut, that carbon is combustible in perfectly dry oxygen.—M. Chevreul made some remarks on this paper.—A note by MM. L. Dusart and C. Bary on the transformation of phenole into alkaloïds was presented by M. Cahours. The authors have obtained phenylamine, chloride of phenyle, and diphenylamine by the action of hydrochlorate of ammonia and fuming hydrochloric acid upon phenole.—M. P. Barbier announced his having produced cymene by treating hydrate of essence of turpentine with bromine.—A letter was read from M. V. Meyers on the reaction between sulphur and aqueous vapour in the synthesis of sulphuric acid, and on the

preparation of pure zinc by electrolysis.—An important discussion on the vexed question of spontaneous generation was raised by the reading of some reflections concerning heterogenesis by M. A. Trécul. In the discussion MM. Balard, Fremy, and Blanchard took part.—A somewhat cognate matter was also treated by M. A. Béchamp in his paper on the cause of alcoholic fermentation by beer-yeast, and on the formation of leucine and tyrosine in this fermentation.—M. C. Robin presented a note by M. S. Chantran on the fecundation of the crayfish, in which the author describes the impregnation of the ova as taking place after their expulsion from the oviducts.—A note by MM. E. Mathieu and V. Urbain on the gases of the blood, was presented by M. Cahours.

THURSDAY, FEBRUARY 1, 1872

THE INTERNAL FLUIDITY OF THE EARTH

WE have been favoured with permission to reprint the following extract from a letter addressed by Sir Wm. Thomson to Mr. G. Poulett Scrope:—

The University, Glasgow, Jan. 15, 1872

DEAR SIR,—I thank you very much for the copy of your beautiful book on Volcanoes, which you have been so kind as to send me through Professor Geikie. It is full of matter most interesting to me, and I promise myself great pleasure in reading it.

I see with much satisfaction, in your prefatory remarks, that you "earnestly protest against the assertion of some writers, that the theory of the internal fluidity of the globe is or ought to be generally accepted by geologists on the evidence of its high internal temperature." Your sentence upon the "attractive sensational idea that a molten interior to the globe underlies a thin superficial crust; its surface agitated by tidal waves and flowing freely towards any issue that may here and there be opened for its outward escape," in which you say that you "do not think it can be supported by reasoning, based on any ascertained facts or phenomena," is thoroughly in accordance with true dynamics. It will, I trust, have a great effect in showing that volcanic phenomena, far from being decisive, as many geologists imagine them to be, in favour of a thin crust enclosing a wholly liquid interior, tend rather, the more thoroughly they are investigated, to an opposite conclusion.

I must, however, take exception to your next sentence, that in which you say that "M. Delaunay has disposed of the well-known astronomical argument of Mr. Hopkins and Sir W. Thomson, as to the entire or nearly entire solidity of the earth, derived from the nutation of its axis." Delaunay's deservedly high reputation as one of the first physical astronomers of the day, has naturally led many in this country to believe that his objection to the astronomical argument in favour of the earth's rigidity cannot but be valid. It has even been hastily assumed that the objection is founded on mathematical calculation, an error which the most cursory reading of Delaunay's paper corrects. His hypothesis of a viscous fluid breaks down utterly when tested by a simple calculation of the amount of tangential force required to give to any globular portion of the interior mass the precessional and nutational motions, which, with other physical astronomers, he attributes to the earth as a whole. Thus: taking the ratio of polar diameter to equatorial diameter as 299 to 300, and the density of the upper crust as half the mean density of the earth, I find (from the ordinary elementary formulæ) that when the moon's declination is $28\frac{1}{2}$, the couple with which she tends to turn the plane of the earth's equator towards the plane of her own centre and the equinoctial line has for its moment a force of 285×10^{18} times the gravity of one gramme at the earth's surface, or rather more than a quarter of a million million tons weight, on an arm equal to the earth's radius. A quadrant of the earth being ten thousand kilometres, the area is

five hundred and nine million square kilometres, or $5 \cdot 09$ million million square centimetres. Hence a force of 285×10^{18} grammes weight distributed equally over two-thirds of the earth's area would give $\cdot 084$ of a gramme weight per square centimetre. This supposition is allowable (for reasons with which I need not trouble you) in estimating roughly the greatest amount of tangential force acting between the upper crust and a spherical interior mass in contact with it, from the preceding accurate calculation of the whole couple exerted by the moon on the upper crust. It is thus demonstrable that the earth's crust must, as a whole, down to depths of hundreds of kilometres, be capable of transmitting tangential stress amounting to nearly $\frac{1}{10}$ of a gramme weight per square centimetre. Under any of such stress as this any plastic substance which could commonly be called a viscous fluid would be drawn out of shape with great rapidity. Stokes, who discovered the theory of fluid viscosity, and first made accurate investigations of its amount in absolute measure, found that a cubic centimetre of water, if exposed to tangential force of the millionth part of $\frac{1}{10}$ of a gramme weight on each of four sides, would even under so small a distorting stress as this, become distorted so rapidly that at the end of a second of time its four corresponding right angles would become one pair of them acute and the other obtuse, by as much as a two-hundredth part of the angle whose arc is radius, that is to say by $\cdot 29$ of a degree. Not as much as a ten-million-millionth part of this distortion could be produced every second of time by the lunar influence in the material underlying the earth's crust without very sensibly affecting precession and nutation; for the effect of the maximum couple exerted on the upper crust by the moon is to turn the whole earth in a second of time through an angle of a one-hundred-million-millionth of $\cdot 57$ of a degree, so as to give to it at the end of a second the position obtained by geometrically compounding this angular displacement with the angular displacement due simply to rotation. Hence the viscosity assumed by Delaunay, to produce the effect he attributes to it, must be more than ten million million times the viscosity of water. How much more may be easily estimated with some degree of precision from Helmholtz's mathematical solution of the problem of finding the motion of a viscous fluid contained in a rigid spherical envelope urged by periodically varying couples.* The most interesting part of the application of this solution to the hypothetical problem regarding the earth, is to find how rapidly the obliquity of the ecliptic would be done away with by any assumed degree of viscosity in the interior; such an amount of viscosity, for example, as would render the excesses of precession and nutation above their values for a perfectly rigid interior, not greater than observation could admit.

The hypothesis of a continuous internal viscous fluid being disposed of, the question occurs, what rigidity must the interior mass have, even if enclosed in a perfectly rigid crust, to produce the actual phenomena of precession and nutation? The solutions given by Lamé and myself of the problem of the vibrations of an elastic solid globe, may be readily applied to determine the influences on precession and on the several nutations, which would be produced by elastic yielding with any assumed rigidity

* Helmholtz and Piotrowski, "Ueber Reibung tropfbarer Flüssigkeiten," Imp. Acad. Vienna, 1860.

short of infinite rigidity. This application I have no time at present to make; but without attempting a rigorous investigation, it is easy roughly to estimate an inferior limit to the admissible rigidity. In the first place, suppose, with perfect elasticity, the rigidity be so slight that distorting stress of $\frac{1}{10}$ of a gramme weight would produce an angular distortion of a half degree or a degree. The whole would not rotate as a rigid body round one "instantaneous axis" at each instant, but the rotation would take place internally, round axes deviating from the axis of external figure, by angles to be measured in the plane through it and the line perpendicular to the ecliptic in the direction towards the latter line. These angular deviations would be greater and greater the more near we come to the earth's centre, and the greatest angular deviation would be comparable with 1° . Hence the moment of momentum round the solstitial line would be sensibly less than if the whole mass rotated round the axis of figure. Now suppose for a moment our measurement of force to be founded on a year as the unit of time. We find the amount of precession in a year by dividing the mean amount of the whole couple due to the influence of moon and sun by the moment of momentum of the earth's motion round the solstitial line. Hence the amount of precession would be sensibly augmented by the elastic yielding; for the motive couple is uninfluenced by the elastic yielding, if we suppose the earth to be of uniform internal density. An ordinary elastic jelly presents a specimen of the degree of elasticity here supposed, as is easily seen when we consider that the mass of a cubic centimetre of such material is a gramme, and therefore that the weight of a cubic centimetre of the substance is the "gramme weight" understood in the specification $\frac{1}{10}$ of a gramme weight per square centimetre. If then, the interior mass of the earth were no more rigid than an ordinary elastic jelly, and if the upper crust were rigid enough to resist any change of figure that could sensibly influence the result, the precession would be considerably more rapid than if the rigidity were infinite throughout. The lunar nineteen-yearly nutation proves a higher degree of elasticity than this; the solar semi-annual nutation still a higher degree; and still higher yet the imperceptibility of the lunar fortnightly nutation; provided always we suppose the interior mass to be of uniform density, and the upper crust rigid enough to permit no influential change of figure.

The motive of the nineteen-yearly precession may be mechanically represented by two circles of matter pivoted on diameters, fixed in the plane of the earth's equator, bisecting one another perpendicularly at the earth's centre. These two circles must oscillate round their pivot-diameters, each through an angle of about 5° on one side and the other of the plane of the equator, in a period of about nineteen years, to produce the lunar nineteen-yearly nutation (more nearly eighteen years seven months). If the radius of each of the supposed material circles is equal to the moon's mean distance from the earth, the mass of each must be a little less than the moon's mass, and one of them a little less than the other.* The diameter on which the latter is pivoted is to be the equinoctial line. The latter alone causes the nutation in right ascension; the former the nutation

in declination. The phases of maximum and of zero deflection, in the oscillations of the two circles, follow alternately at equal intervals of time, so that when either is in the plane of the earth's equator, the other is at its greatest inclination of 5° on either side. Taking one of the constituents of the nutational motive alone, we find, on the principles indicated above, $\frac{1}{100}$ of a gramme weight per square centimetre as a very rough estimate for the greatest tangential stress produced by it in the material underlying the earth's crust. Now it is clear that the central parts of the earth and the upper crust cannot, in the course of the nutatory oscillations, experience relative angular motions to any extent considerable in comparison with the nutation of the upper crust, without considerably affecting the whole amount of the nutation. The nutation in declination amounts to $9''.25$ on each side of the mean position of the earth's poles, and therefore the tangential stress of $\frac{1}{100}$ of a gramme weight per square centimetre cannot produce an angular distortion considerable in comparison with $9''$.

An angular distortion of $8''$ is produced in a cube of glass by a distorting stress of about ten grammes weight per square centimetre. We may, therefore, safely conclude that the rigidity of the earth's interior substance could not be less than a millionth of the rigidity of glass without very sensibly augmenting the lunar nineteen-yearly nutation. The lunar fortnightly nutation in declination amounts theoretically to about $1''$, and it is so small as to have hitherto escaped observation. It probably would have been so large as to have been observed were the interior rigidity of the earth anything less than $\frac{1}{200000}$ of that of glass, always provided that the upper crust is rigid enough to prevent any change of form sensibly influencing the nutational motive couple. To understand the degree of rigidity meant by " $\frac{1}{200000}$ of the rigidity of glass," imagine a sheet of some such substance as gutta-percha or vulcanised india-rubber of a square metre area and a centimetre thickness. Let one side of the sheet be cemented to a perfectly hard plane vertical wall, and let a slab of lead 8.8 centimetres thick (weighing therefore a metrical ton)* be cemented to the other side of it. If the rigidity of the substance be $\frac{1}{200000}$ of the rigidity of glass,† and the range of its elasticity sufficient, the side of the sheet to which the lead is attached will be dragged down relatively to the other through a space of $\frac{1}{12}$ of a centimetre.

In the argument from tidal deformations of the solid part of the earth's material, which I communicated to the Royal Society ten years ago, and mentioned incidentally at the recent meeting of the British Association, I showed that though precession and nutation would be augmented by want of rigidity in the interior, they would be diminished by want of rigidity in the upper crust, and that on no probable hypothesis can we escape the conclusion that the earth as a whole is less yielding than a globe of glass of the same dimensions and exposed to the same forces. That argument, therefore, proves about 200,000 times greater rigidity for the earth as a whole than what I

* The metrical ton, or the mass of a cubic metre of water at temperature of maximum density, is $984\frac{1}{2}$ of the British ton. The thickness of a slab of lead of a square metre area, weighing a metrical ton, is, of course, equal to a metre divided by the specific gravity of lead.

† Everett's measurements give 244×10^6 centimetres weight per square centimetre for the rigidity of the glass on which he experimented. Instead of this I take 240×10^6 for simplicity.

* The greater is equal to the moon's mass multiplied by the cosine of the obliquity of the ecliptic; the less is equal to the moon's mass multiplied by the cosine of twice the obliquity of the ecliptic.

have now written to you proves for the interior of the earth on the supposition of a thin preternaturally rigid crust.

I must apologise to you for having troubled you with so long a letter. I did not intend to make it so long when I commenced, but I have been led on by considerations of details, inevitable when such a subject is once entered upon.—I remain, yours very truly,

WILLIAM THOMSON

G. Poulett Scrope, Esq., F.R.S.

THE SOLAR ECLIPSE

IN the communication to NATURE, written from Ootacamund, I promised another when I was in possession of more information as to the work done, not only by the British Association parties, but by those representing the Indian and French Governments. Let me now endeavour to redeem my promise, seeing that since that communication was penned I have had the happiness of hearing from Mr. Janssen's own lips an account of what he did; have met Captain Waterhouse, the last representative at Ootacamund of Colonel Tennant's party; have visited Mr. Pogson at Madras, who obligingly gave me an account of the results obtained at Avenashi; and last, but not least, have learnt since my return home that the Jaffna party were successful, not only with the polariscope, but also with the camera and spectroscop.

Within a few minutes of the despatch of my last article I found that Captain Waterhouse, who assisted Mr. Hennessy in exposing the photographic plates taken by Colonel Tennant's party, was still at Ootacamund, and this welcome intelligence was soon followed by Captain Waterhouse himself, who was so good as to bring with him a drawing of one of the photographs; the plates themselves having been taken down the ghaut by Colonel Tennant, with the intention of comparing them at Pothonore with those taken by Mr. Davis. Unfortunately, as has been already stated, we missed each other, and so an absolute comparison of photographs did not take place; but from the drawing it was evident that in the two series the main form of the corona was the same. The photographs I learned were very sharp and good, and one appreciates their value the more when it is known that only a very little time before they were taken, any success, even a partial one, seemed out of the question, so persistently did cloud and mist hang over Dodabet on the eventful morning. I gathered that the spectroscopic observations had also been successful, and that a continuous spectrum with 1474 had been observed. If more lines than this were not seen, it is easily to be accounted for by the relatively long focal length of the object-glass employed to throw an image of the eclipsed sun on the slit.

Not until the morning after my interview with Captain Waterhouse did I learn the whereabouts of Dr. Janssen, who, from a study of the habits of the clouds and their prevailing drift, had concluded that the neighbourhood of Ootacamund was not the best that could be chosen. He had consequently taken his departure, and it seemed at first as if his whereabouts was known to no one. At last, however, Prof. Respighi and myself came upon his spoor; he was at Sholor, on the N.E. flank of the range, at the solitary house of a tea-planter, to which there was no road, but which might be reached on ponies if a guide

to it could be found. This guide Captain Sargeant, of the Revenue Department, obligingly provided, and in no very long time we reached the beautiful spot which Dr. Janssen had chosen.

It will be better that I should state his results in his own words. In a letter* to Prof. De La Rive, dated December 26, he thus writes:—

"J'ai été favorisé par un ciel d'une pureté presque absolue. Cette circonstance, et surtout les dispositions optiques toutes nouvelles que j'avais prises, m'ont permis de faire sur la couronne des constatations qui démontrent son origine solaire (pour la meilleure partie).

"Dans mon télescope,† le spectre de la couronne s'est montré non pas continu, mais remarquablement complexe. J'y ai constaté:

"Les raies brillantes du gaz hydrogène qui forme le principal élément des protubérances et de la chromosphère.

"La raie brillante verte déjà signalée aux éclipses de 1869 et 1870, et quelques autres plus faibles,

"Des raies obscures du spectre solaire ordinaire, notamment D. Ces raies sont beaucoup plus difficiles à apercevoir.

"Mes observations prouvent que, indépendamment des matières cosmiques qui doivent exister dans le voisinage du Soleil, il existe autour de cet astre une atmosphère très étendue, excessivement rare, à base d'hydrogène.

"Cette atmosphère, qui forme sans doute la dernière enveloppe gazeuse du Soleil, s'alimente de la matière des protubérances, lancée avec une si grande violence, des entrailles de la photosphère. Mais elle se distingue de la chromosphère et des protubérances, par une densité énormément plus faible, une température moins élevée, et peut-être par la présence de certain gaz différents.

"Il y a donc lieu de distinguer cette nouvelle atmosphère solaire. Je propose de la nommer *atmosphère coronale*, désignation qui rappelle que c'est elle qui produit la meilleure partie des phénomènes lumineux qui ont été désignés jusqu'ici sous le nom de couronne solaire.

"En annonçant ce résultat, je n'oublie pas, quant à moi, tout ce que nous devons aux travaux qui l'ont préparé, notamment ceux des astronomes américains aux éclipses de 1869 et 1870."

It will be seen that the importance of the brilliancy of the image, so strongly insisted upon by the Eclipse Committee in their Instructions, had been fully recognised by Dr. Janssen, whose instrument had more light even than those used by the British parties, who used "Browning With" reflectors of 9½ inches aperture, and some 6 feet focus.

Although my account, in this place and at this time can only be of the most general character, the coincidence obtained by Janssen, Respighi, and myself on one point may be briefly referred to, namely, the distinct proof obtained by each of us that above the most vivid chromospheric layer, and even the prominences, we have hydrogen with its most familiar bright lines, and with much of the "structure" of its spectrum; these proofs being derived not only from the old method of inquiry, but from the new one employed by Professor Respighi and myself.

We spent the remainder of the day at Sholor in mounting the hill at the back of the house to see the observatory, and to admire the wonderful view of the plains of Mysore, which was visible between a break in the hills; while the immediate neighbourhood, with its water-

* Bibliothèque Universelle, January 15, 1872, p. 103.

† Ce télescope a une ouverture de 0^m 37, et 1^m 42 seulement de distance focale. Les images y sont de 12 à 16 fois plus lumineuses que dans une lunette astronomique ordinaire. Le spectroscopie avait été construit pour utiliser toute cette lumière.

falls, massive peaks, rocks here, and patches of wood there, steep ravines and tea-clad valleys, presented us with a scene of perfect beauty.

Next morning we were away before sunrise on our way to Mr. Pogson, whom we found at the Madras Observatory, preparing to exchange time signals with the Jaffna party. Three photographs were taken by Mr. Pogson at Avenashi, but the instrument used was so different from those used at Bekul and Dodabet (not to mention Jaffna) that it is difficult to institute a comparison in the time at my disposal; but it is not to be doubted that they will be of the highest importance when the general results come to be discussed. Mr. Pogson was assisted in the observations by his son and Mr. Chisholm, the Government architect, who was highly successful in sketching the corona and the eclipse effects upon the landscape.

Come we last to Jaffna. In my former article I referred only to the polariscope and spectroscope work done there. I have since learned that six photographs were taken with the sister instrument to the one used at Bekul.

The observations, in fact, were a perfect success. The morning was clear and bright, and could not have been finer had any one so wished.

At about six o'clock the party and those who were to assist them began to assemble on the Belfry Bastion in the Fort. Capt. Tupman observed with a polariscope and drew during the eclipse, and was assisted by Capt. Varian of the *Serendib* as his time-keeper; Mr. Lewis with his telescope and polariscope was stationed inside the hut, with the photographic party, and Mr. Thwaites, Deputy Queen's Advocate, who was assisted by the carpenter of the *Serendib*. Capt. Fyers, R.E., with the spectroscope, had for his assistant Mr. W. S. Murray, Deputy Fiscal; and Capt. Hogg, R.E., who presided over the photographic department, was assisted by Mr. Twynam, Government agent, and Mr. J. W. Simpson. By these observers the polariscope results were arrived at, a telegraphic summary of which I quoted in my last communication. Six photographs were taken, being one more than we obtained at Bekul; and in the clockwork-driven integrating spectroscope the reversal of the dark lines was seen at the beginning of totality, and the hydrogen bright lines and 1474 during totality. No information yet about intensities.

Sketches were made by Mr. Foenander, of the Surveyor-General's Department, Colombo; Mr. Pargiter, Assistant Government Agent; Mr. Vine, M.C.E., of the Public Works Department; Mr. Carmichael and Mr. Layard of the O.B.C.

The crowd of natives round the Belfry Bastion was very great; they set up a most hideous howl directly totality commenced, fancying that the end of the world was at hand. They were under the impression that the whole of the Expedition with assistants and all here during the eclipse were going to get into a balloon and off to the sun and not return.

It will thus be seen that the hopes of those interested in the various expeditions of this year have not been disappointed. The composition and structure of a part of the corona have been for ever set at rest, while we have seventeen photographs, taken by instruments of the same power and pattern, to compare with each other—eleven

taken at the ends of a base line some 400 miles long, and six at an intermediate elevated point, whereby it was hoped to test the influence of the atmosphere on the observed phenomena. Whether the slight mist will have prevented this or not remains to be proved; but anyhow here is a wealth of records unequalled before, and we may hope to learn much of the outer coronal regions from their comparison, not only *inter se*, but with Mr. Holiday's admirable drawings, showing considerable changes, which have also come to hand.

J. NORMAN LOCKYER

THE ADMIRALTY MANUAL OF SCIENTIFIC INQUIRY

A Manual of Scientific Inquiry; Prepared for the Use of Officers in Her Majesty's Navy and Travellers in General. 4th Edition. Superintended by the Rev. Robert Main, M.A., F.R.S., Radcliffe Observer at Oxford. Pp. 392. (John Murray, 1871.)

IN one of the earlier numbers of the *Philosophical Transactions* may be found a long list of observations proposed to be made by travellers who were about to visit the Peak of Teneriffe. Athanasius Kircher, in his *China Illustrata*, had given an account of such great marvels, that the less credulous, even of those days, wondered and almost doubted; and it was thought to be of advantage to know whether unicorns and dragons really did exist in foreign parts, whether diamonds grew, and what was the precise nature of that "poyson which turneth a man's blood to gelly." Long afterwards the Royal Society issued instructions for the Antarctic Expedition, hints for collecting information in China, and a book entitled "What to Observe," but there was no general manual for the use of observant travellers, directing them specially not only what to observe, but how to observe. In 1849 the Lords Commissioners of the Admiralty, conceiving that "it would be to the honour and advantage of the Navy, and conduce to the general interests of Science, if new facilities and encouragement were given to the collection of information upon scientific subjects by the officers, and more particularly by the medical officers, of Her Majesty's Navy when upon foreign service," gave orders for the compilation of "The Admiralty Manual." The work was originally edited by Sir John Herschel, and was divided into various sections, each the work of some competent authority.

The work is divided into four parts. The first includes astronomy, hydrography, and tides; the second terrestrial magnetism, meteorology, atmospheric tides; the third geography, statistics, medical statistics, ethnology; and the fourth geology, mineralogy, seismology, zoology, botany. In this last edition all the articles are brought *en rapport* with the progress of science since 1849; the article on tides by Dr. Whewell is revised by the present editor of the book; the articles on statistics, medical statistics, ethnology, geology, mineralogy, botany, have also been revised by other than the original authors. There are two capital maps, the one to illustrate hydrographic delineation; the other to show the approximate limits of the great currents and drifts of the ocean.

The Astronomy (by the Astronomer Royal) is the shortest article in the book, extending over no more than 12 pages. Hydrography, on the other hand, occupies 49 pages, and contains much useful information regarding soundings, the discovery of land, sailing directions, and artificial harbours. The directions are essentially practical and eminently suggestive; thus, take the following from *Approaching a coast*:—"Always bear in mind that no description can equal a tolerably faithful sketch, accompanied by bearings. In all four sketches take angles roughly with a sextant between objects at the extremities of four drawings, and two or more intermediate ones, and affix them to the objects of the moment, and have at least one angular height in the picture; let that be of the highest and most conspicuous or best defined object."

The article on Tides (26 pages) gives minute directions for tide observations and the construction of curve tables. The next section, on Terrestrial Magnetism, by Sir Edward Sabine, is of great importance, and describes the methods of observation most in vogue; the observations of local attraction, of vibration, of deflection, and so on. We miss, however, any account of the magnetism of iron ships, and the elimination of the compass error caused thereby. Also we feel assured that simple instructions for travellers as to the use of compasses on land, in the midst of forests, &c., would prove of much service. Under the heading Meteorology we find directions for observing systematically a large number of aerial phenomena, water-spouts, bull's-eye signals, showers of dust and ashes, cyclones, various electrical manifestations, &c. Passing over the articles on atmospheric waves and barometric curves, we come to that on Statistics, which is of very general interest, and relates to the state of education and crime of a people, the manufactures, commerce, currency, revenue, municipal regulations, &c. This is followed by "Medicine and Medical Statistics," regarding the various fevers and other diseases to which travellers are specially exposed, with hints for determining the geographical distribution of diseases.

The chapter on Ethnology by the late J. C. Prichard, revised by Mr. E. B. Tylor, is to be specially commended to the notice of travellers; under the term he includes "all that relates to human beings, whether regarded as individuals, or as members of families or communities;" the physical and social history of man. This chapter is divided into three parts:—(1) of the Physical Character of Nations; (2) Characteristics of the state of Society, &c.; (3) Language, Poetry, Literature. We are lamentably deficient in our knowledge regarding the earlier history of the physical sciences, and are glad to find that Mr. Tylor alludes to the acquirement of knowledge of this nature in the following paragraph:—"The crude notions entertained by uncivilised races on subjects within the scope of physical science are matters worthy of inquiry. Science they can hardly be said to possess, though this was scarcely true with the ancient Mexicans. All nations observe the changes of the moon, and measure the lapse of time with a greater or less degree of accuracy by the movements of some of the heavenly bodies. The special names given to the months, if any, should be recorded. Inquiry should be made whether the motions of the planets are observed, and whether these bodies are distinguished from fixed stars; what ideas are current as

to the conformation of earth and sky and the cause of eclipses; whether attempts are made to ascertain the duration of the solar year, whether there are names for the constellations, and what they are if they exist."

Of the remaining portions of this work we need only allude to that devoted to "Seismology, or Earthquake Phenomena," by Mr. Robert Mallet, which contains many details as to the observation of effects of rare occurrence in these latitudes, but to the traveller in South America the suggestions would be invaluable. Thus we have an account of instruments for observing the velocity and direction of the shock of an earthquake, observations to be made in a city affected by an earthquake, and the preparation of coseismal and meizoseismal curves. To conclude: the whole work is wonderfully suggestive, not alone to the traveller, but to the home observer; it teaches us to arrange in order and systematise our observations, and in so doing conveys a great deal of collateral information.

G. F. RODWELL

OUR BOOK SHELF

Gmelin-Kraut's Handbuch der Chemie, Anorganische Chemie. In Drei Bänden, Sechste ungeveränderte Auflage. Herausgegeben von Dr. Karl Kraut, Heidelberg. Erster Band zweite Abtheilung, pp. 176. (London: Williams and Norgate.)

It is now eighteen years since the appearance of the fifth edition of this work; this, of course has necessitated the change from the old atomic weights to the new, but the arrangement of the elements and sections of the book has been retained as in former editions. The present volume has been thoroughly revised, the information having been brought up to a very recent date; should the remaining volumes be equally reliable, it will probably be the most complete work on inorganic chemistry in any language. Dr. Kraut has obtained the assistance of Drs. Naumann, Ritter, and Jorgensen, in order to expedite the conclusion of the work. There is no book to our knowledge which contains so large an amount of information in a small space as Gmelin's Handbook. It is, as expressed in the preface, a complete, concise, and systematic handbook of chemistry up to the latest time. The merits of this book for the purposes of reference are so well known that it would be quite superfluous to enter into any lengthened description of it. In the volume now under consideration oxygen, hydrogen, carbon, boron, phosphorus, and sulphur, with some of their more important compounds, are treated of; the article on ozone and its properties is perhaps typical of the book, it occupies fourteen pages, and forms a very valuable and complete history of this body. The completion of the book may be looked for with interest, although necessarily it will be some time before this can be accomplished.

Astronomical Phenomena in 1872. By W. F. Denning, Hon. Sec. of the Observing Astronomical Society. (London: Wyman and Son.)

THIS brochure consists of some general remarks on astronomical observing, and some forty pages of data almost entirely taken from the "Nautical Almanack" for 1872. The former are addressed to the simplest tyro, and are so meagre as to give the impression of a want of accurate knowledge. In the section touching upon instruments we are told that "with regard to the spectroscope, micrometer, and other astronomical appliances, it will be better to say but very

little." Accordingly very little is said, and that little is unimportant. Speaking of objects, Mr. Denning startles us with the announcement that "Comets are not interesting objects in a telescope" (we should like to hear upon what experience he grounds this assertion); and he deals with the hypothetical plant Vulcan by naively telling his disciples that when a total eclipse of the sun "is in progress, the region of the heavens in the immediate vicinity of the solar orb should be subjected to very careful scrutiny." For such untutored gazers as are addressed in the earlier pages the data in the later sections are insufficient. There are no times of rising and setting of the moon and planets, no positions of Jupiter's satellites at times of eclipse, no information upon the points on the moon's limb at which occulted stars will disappear and reappear, no warning of the effects which change of geographical position will produce in some phenomena which are computed for Greenwich only. Altogether the book is a very weak production. J. C.

Die Arachniden Australiens nach der Natur beschrieben und abgebildet, von Dr. L. Koch. Erste Lieferung. Pp. 56. Plates iv. (Nurnberg, 1871.)

DR. L. KOCH intends in this work to describe the spiders of Australia, not confining himself apparently to the large insular tract that generally passes under this name, but taking in also the Viti Islands, the Friendly, Pelew, and other groups. In his Preface to this, the first portion of his work, he says that though he has with much care and industry for twenty years observed the Arachnida of a little circuit of not more than from four to five hours walk, yet every year there comes to light within this small compass some new species that had up to then remained concealed; indeed it often happened that each little journey increased the number of forms known in the district. How true this observation is every investigator will feel; but knowing and feeling it, what courage does it not require to set to work to write the history of the spiders of a district which itself is not even yet half explored; and when the spiders are done, we are promised another work on the Myriapods. Such courage deserves to succeed, and we wish the enterprise every prosperity. The work will be published at intervals of two months, and be completed in two years; each bi-monthly part will contain four plates and some five sheets of text.

Following the families and genera as laid down by Thorell in his "European Spiders," L. Koch commences with the Epeiridae, and describes six new species of the interesting genus *Gasteracantha*. Here, as in the other genera, the new species are well figured by the author in quarto plates. It is to be observed that some of the species described are not to be met with, at least have not at present been met with, in any part of Australia, but are introduced into this work by the head and shoulders as it were thus:—*G. violenta* comes from New Guinea, and *G. hepatica* from Java. Two new genera, *Tholia*, with three species, and *Anepeira* for *Epeira rhomboides*, L.K., are given. Ten new species of the genus *Argiope* are described, and three new species of *Cyrtarachne*. The diagnoses of the new genera are very properly given in Latin, and the work may be regarded as quite indispensable to all those engaged in the study of the spiders. W.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

Change of Habits in Animals and Plants

SOME weeks since I sent a few notes on *Nestor notabilis*,* showing a curious change in the history of this mountaineer. I now beg to add an extract from the *Otago Daily Times*, in confirma-

tion of this strange story of the progressive development of change in the habits of the Kea, from the simple tastes of a honey-eater to the savageness of a tearer of flesh:—

"Some time ago we mentioned that Mr. Henry Campbell, of Wanaka Station, had noticed that sheep, on his run were frequently attacked by birds. We are indebted to Mr. Campbell for some further information on the subject. The birds in question are of the kind called by shepherds "the mountain parrot," and the scientific name of which is *Nestor notabilis*. The Maories call it the Kea. The birds come in flocks, single out a sheep at random, and each alighting on its back in turn, tears out from the wool and makes the sheep bleed, till the animal runs away from the rest of the sheep. The birds then pursue it, continue attacking it, and force it to run about till it becomes stupid and exhausted. If in that state it throws itself down, and lies as much as possible on its back to keep the birds from picking the part attacked, they then pick a fresh hole in its side, and the sheep, when so set upon, in some instances dies. When the sheep stops bleeding the birds appear to cease to attack it, though Mr. Campbell is not very clear upon this point, and thinks they attack it more for sport than hunger. For three winters back his sheep have been attacked in this way, and it was not till this winter (though he previously suspected it) that he found the birds were the offenders. Where the birds so attack the sheep, the elevation of the country is from 4,000 to 5,000 feet above the sea level, and they only do so there in winter time. On a station owned by Mr. Campbell about thirty miles distant from the other, and at the same altitude, in the same district, and where the birds are plentiful, they do not attack the sheep in that way. For those on whose stations they are an annoyance, it may be mentioned that their numbers can be kept well thinned by shooting them. If one is wounded the rest gather round, and can be shot in fives and sixes at a time."

This note is interesting in the face of the destructive influence commonly exerted by introduced upon native life. Here we have an indigenous species making use of a recently imported aid for subsistence, at the cost of a vast change in its natural habits.

In the vegetable world we meet with a change in the habit of a native species* which is somewhat analogous.

Our *Loranthus micranthus* sometimes neglects its customary supports, found often on such trees as *Melicope* or *Melicope* (representatives of *Violariaceae* and *Rutaceae*), for the more attractive exotics, *Cytisus*, *Crotagus*, the plum, and the peach. Such change in its habits this fragrant parasite acquires at the cost of deserting the interlaced boughs of tangled gully for a more conspicuous position in the trim shrubbery or cultivated garden. At this time I can see a most vigorous specimen of *L. micranthus* growing on *Cytisus laburnum*, covered with countless panicles of perfume-laden blossoms, on which our introduced bee is luxuriously regaling. Here we have the foreign bee gathering sweets from native flowers growing on an exotic tree.

In this neighbourhood the laburnum was first planted, I believe, by myself, in 1859, and the bee introduced about the same time.

Ohinaitahi, Oct. 7, 1871

THOMAS H. POTTS

A Case of Stationary Wave on a Moving Cord

IT is well known to mathematicians that a stretched cord, moving lengthwise with a velocity bearing a certain relation to its tension and weight, will retain any curvature which may be impressed upon it; and consequently would pass through a crooked tube without pressure against its sides. That this may

be the case, the velocity, V , must equal $\sqrt{\frac{T}{M}}$; T being the tension, and M the weight of the cord per unit of length.

Passing from a stationary curve on a moving cord to one moving along a fixed cord, it is easy to see that this velocity, V , must be that of the transmission of a transverse vibration; and from this immediately follows the formula for the times of vibration of stretched strings.

The case of the stationary wave, however, though simple in theory, is rarely practically realised; and I think a short notice of a case in which it is constantly produced may not be without interest.

In Captain Denmet's admirable invention for saving life from shipwrecks, a rocket is employed having a light line attached to it. This line is previously "faked down" on two rows of pins in a box; and, the pins being withdrawn, it remains in a series

* See NATURE, vol. iv., pp. 489, 506.

* See Trans. New Zealand Institute, vol. iii., p. 190.

of zigzags which yield without entanglement to the very rapid motion of the rocket—the strain on the cord being only due to its inertia. As then the force required to set it in motion is proportional to the weight of cord moved multiplied by its velocity, and this weight is also proportional to its weight per unit of length multiplied by the velocity, the strain or tension, $T = MV^2$

or $V = \sqrt{\frac{T}{M}}$; the relation which we have already seen is

necessary to the production of a stationary wave. Accordingly, we find that the rope, instead of at once following the flight of the rocket, rises almost perpendicularly from the box, and only passes into its low trajectory at a distance of six or eight feet, with a sharp irregular curve, which remains comparatively steady during the whole flight of the rocket. This curve is no doubt first produced in the first portion of the rope, which is “faked down” on the ground outside the box; but it would be impossible to see its formation, because of the smoke of the discharge, even if the motion were not too rapid.

One rather curious result of the above-mentioned conditions is, that however erratic the flight of the rocket may be, the rope will continue to follow through the whole track, as if the air were a solid which the rocket had pierced.

Another result is, that no lateral vibrations can be propagated along a rope line—a fortunate condition with regard to steadiness of flight.

Clementhorpe, North Shields, Jan. 26

Ocean Currents

PROF. EVERETT has evidently misapprehended what I said in my letter to NATURE, January 11. Nine foot-pounds would, of course, generate in a pound of matter a velocity equal to that acquired by the pound falling through a space of nine feet. And in reference to the deflecting power of rotation, what I meant was not the amount of deflection in a given space passed over, but the positive amount, say in feet, in a given time.

JAMES CROLL

ON TEACHING GEOLOGY AND BOTANY AS PARTS OF A LIBERAL EDUCATION

ON Monday, Jan. 22, one of a series of lectures on Educational questions was given at the rooms of the Society of Arts by Mr. J. M. Wilson, of Rugby. The following may be taken as an abstract of the lecture:—

Two points have to be considered: (1) When, if at all, these Natural History Sciences ought to be introduced into schools; (2) What they should include, and how they should be arranged for teaching purposes.

The problem before schoolmasters is to adjust the rival claims of the subjects which press for admission into the school course, all of which may urge something in their favour. These subjects have increased in number and extent so that the question of re-arrangement is pressing. For the solution at present is to admit a little of all, or nearly all; and the effect of this is to distract. A wide education levels up, but also levels down, and weakens, by eliminating the close study of detail, and the drudgery that is essential in valuable work. It is that conflict between the old theory of *promise* and the new theory of *performance*; and schools are in great danger of giving less faculty than they did formerly, though they give increased knowledge.

To meet the requirements some *stratification* of studies must be effected, so that not so many shall be followed at once. Greek and Chemistry and Physics (except Mechanics), should be excluded from the elementary course, which should include Latin, French, Arithmetic, and Natural History. Then bifurcation should begin; the one branch leading to Greek and a mainly literary education, the other to Science; both continuing Latin and English, and French and History. The recognition of the bifurcation, both by the Universities and by the great schools,

is urgently needed. Without it Science must be dwarfed or excluded, and literature also suffer from the distraction which is already felt at schools. The programme of the reformers in education ought to include the abolition of Greek as a compulsory subject at the Universities.

By Natural History is meant what Huxley has introduced to us under the word “Erdkunde.” The earth, its relation to sun and moon, the phenomena of day and night, and seasons; the changes going on, the activities of the earth, rain, and rivers, and sea, and earthquakes, and slow changes of level, and their geological effects, and something also of geology proper. The teaching should be based on the familiar knowledge of the boys, and should extend and systematise it, and without being too dogmatical, should be practical where possible. A little botany, enough to teach the objects and the interests of the science, and the principles of structure and classification, and something of geographical distribution, may well be included in the natural history of this elementary stage in education. The object of the master should be to discover and train scientific ability, as well as to give scientific information, and for this purpose these studies have great advantages. The bearing of the experience gained at Rugby on these questions was also given.

THE SURVIVAL OF THE FITTEST

LAST summer a discussion took place in your pages on the expression, “Survival of the Fittest,” and on the principle it formulates. Though, as being responsible for this expression, there seemed occasion for me to say something to dissipate the errors respecting it, I refrained from doing so, for the reason that the rectification of misstatements and misinterpretations is an endless work, which it is almost useless to commence.

In your last number, however, the question has cropped up afresh in a manner which demands from me some notice. A Professor is tacitly assumed to be an authority in his own department; and a statement made by him respecting the views of a writer on a matter coming within this department, will naturally be accepted as trustworthy. Hence it becomes needful to correct serious mistakes thus originating.

In your abstract of Prof. E. D. Cope’s paper, read before the American Association for the Advancement of Science, I find the following sentences:—

“This law has been epitomised by Spencer as the ‘Preservation of the Fittest.’ This neat expression, no doubt, covers the case, but it leaves the origin of the fittest entirely untouched.”

There are here two misstatements, the one direct and the other indirect, which I must deal with separately.

So far as I can remember, I have nowhere used the phrase, “Preservation of the Fittest.” It is one which I have studiously avoided; and it belongs to a class of phrases for the avoidance of which I have deliberately given reasons in “First Principles,” sec. 58. It is there pointed out that such expressions as “Conservation of Force,” or “Conservation of Energy,” are objectionable, because “conservation” implies a conserver, and an act of conserving—implies, therefore, that Energy would disappear unless it was taken care of; and this is an implication wholly at variance with the doctrine enunciated. Here I have similarly to point out that the expression “Preservation of the Fittest” is objectionable, because in like manner it supposes an act of preserving—a process beyond, and external to, the physical processes we commonly distinguish as natural; and this is a supposition quite alien to the idea to be conveyed. One of the chief reasons I had for venturing to substitute another formula for the formula of Mr. Darwin, was that “Natural Selection” carries a decidedly teleological suggestion, which the hypothesis to be formulated does not in reality contain; and a good deal of the ad-

verse criticism which the hypothesis has met with, especially in France, has, I think, arisen from the misapprehension thus caused. The expression, "Survival of the Fittest," seemed to me to have the advantage of suggesting no thought beyond the bare fact to be expressed; and this was in great part, though not wholly, the reason for using it.

Prof. Cope's indirect statement, that I have said nothing to explain "the origin" of the fittest, is equally erroneous with his direct statement which I have just corrected. In the "Principles of Biology," sec. 147, I have contended that no "interpretation of biologic evolution which rests simply on the basis of biologic induction, is an ultimate interpretation. The biologic induction must be itself interpreted. Only when the process of evolution of organisms is affiliated on the process of evolution in general, can it be truly said to be explained.

... We have to reconcile the facts with the universal laws of re-distribution of matter and motion." After two chapters treating of the "External Factors" and "Internal Factors," which are dealt with as so many acting and reacting forces, there come two chapters on "Direct Equilibration" and "Indirect Equilibration"—titles which of themselves imply an endeavour to interpret the facts in terms of Matter, Motion, and Force. It is in the second of these chapters that the phrase "Survival of the Fittest" is first used; and it is there used as the most convenient physiological equivalent for the purely physical statement which precedes it.

Respecting the adequacy of the explanation, I, of course, say nothing. But when Prof. Cope implies that no explanation is given, he makes still more manifest that which is already made manifest by his mis-quotation—either that he is speaking at second hand, or that he has read with extreme inattention. HERBERT SPENCER

Athenæum Club, Jan. 29

THE CHANCE OF SURVIVAL OF NEW VARIETIES

AN argument first urged by the writer of an article on the "Origin of Species" in the *North British Review* for June 1867, regarding the probability of the preservation of a new modification or variety among the descendants of a plant or animal, has of late attracted much attention. It has been discussed at length by Mr. Mivart, one of the ablest critics of the Darwinian theory, and Mr. Darwin himself has, with characteristic candour, ascribed great, and as I believe undue, importance to the inferences drawn from it.

To some extent I agree with the remarks of Mr. Davis, published in your journal of the 28th December last, but I venture to think that the soundness of the argument in question has not been thoroughly tested, and that it will not bear close examination. The calculus of probabilities is a very subtle instrument, and, even in what appear to be its simpler applications, a very fallacious one, if every step in the process is not carefully considered.

The reviewer started with a seemingly simple statement of the case—"A million creatures are born; 10,000 survive to produce offspring. One of the million has twice as good a chance of surviving; but the chances are

50 to 1 against the gifted individual being one of the ten thousand (at first erroneously printed 'hundred') survivors." The fallacy here lies in the assumption that under the conditions which, according to the Darwinian theory, enable natural selection to become an efficient modifying agent, the chance of survival of a favourable modification can be correctly represented by the ratio of 2 to 1.

To avoid complication let us confine the argument to non-diceous plants or self-fertilising lower animals. The preservation of a new variety or modification of structure depends upon two separate elements related respectively to growth and reproduction. The individual must reach maturity, and must reproduce offspring, and for each of these processes it must be able to overcome the obstacles offered by the action of other organic beings, and by external physical conditions. As a general rule we may assume that the same modification does not affect both growth and reproduction, and as the main stress of the struggle for existence turns on the dangers that affect the early period of growth, and the difficulties attendant on the production of healthy offspring, we shall sufficiently illustrate the subject in hand by considering these separately.

The chance of a modified individual growing to maturity depends upon its power of resistance to, or escape from, the various hostile agencies that surround the young animal or plant, whose combined influence is (by hypothesis) such that but one out of every hundred reaches maturity. Let us assume, for the sake of illustration, that the most important dangers to which the creature is exposed arise from physical conditions—such as excessive drought or damp—and from other organisms, as when it is the favourite food of some common animal. Now let the supposed modification affect the former relation. Let the modified organism be better fitted to resist drought; the result will be an enormous probability in favour of its escape from a danger that may destroy nine-tenths of the unmodified creatures around him, and a similar argument will apply to such a modification as would make the individual modified distasteful, or less than usually attractive, as an article of food. In point of fact, the dangers arising from external physical conditions are usually far less constant in their action than those arising from organic foes, and it is quite conceivable that even in the extreme case of a modification originating in one single individual of a species, if it were such as to give a decided advantage in that direction, the balance of probability would be in favour of survival, and in case of reappearance among numerous individuals in the next generation, have a preponderating chance of ultimate preservation.

The application of figures to measure the advantage given by a modification relating to the capacity of a species for reproduction involves no less difficulty, and may lead to the most various estimates of the probability of survival. A variation in a plant which should double the number of seeds produced without lessening their vitality, would give an advantage of 2 to 1 in the chance of producing offspring, but this, as the reviewer has shown, would not much increase the probability of the ultimate prevalence of that variety. But if the numbers of a plant were chiefly kept down by such a cause as the fruit being a favourite article of food, a modification of its flavour that would lead to some other fruit being preferred would almost certainly lead to the perpetuation of the variety with modified fruit, and not only to the rapid destruction of the unmodified form, but also to a reduction in the prevalence of some other plant.

For it must be recollected that the struggle for existence is not limited to the offspring of a single species. The rivals of each organism are all around, and the chance of survival of a new variety may be enormously increased if it be not only better able to resist hostile

* By way of correcting a further misapprehension of Prof. Cope, I may here point out that this conception, in its less developed form, goes back to a much earlier date than the "Principles of Biology" to which he refers. In the *Westminster Review* for April 1852 (pp. 498-500), I have contended that "this inevitable redundancy of numbers—this constant increase of people beyond the means of subsistence, necessitates the continual carrying-off of 'those in whom the power of self-preservation is the least,' that all being subject to the 'increasing difficulty of getting a living which excess of fertility entails,' there is an average advance under the pressure, since 'only those who do advance under it eventually survive,' and these 'must be the select of their generation.'" There is, however, in the essay from which I here quote, no recognition of what Mr. Darwin calls "spontaneous variation," nor of that divergence of type which this natural selective process is shown by him to produce.

agencies that the unmodified form of the same species, but better than our rival organisms that may be its competitors in the struggle for existence.

I make these remarks without any desire to press the conclusion to an extreme length. I am not one of those more Darwinian than Mr. Darwin himself, who believe that the theory of Natural Selection explains everything, and has left no mysteries unsolved. I feel no doubt but that very many modifications arise that do not perpetuate themselves by the survival of a sufficient number of similarly modified individuals, even in cases where the variation may be slightly favourable; but I cannot admit the validity of an argument that goes to the very root of the principle of Natural Selection, and leads, by the appearance of exact reasoning, to a result that every naturalist feels to be absurd.

In truth, it is impossible to assign any limit to the amount of probability in favour of the preservation of a new variety. In the absence of disturbing causes affecting the equilibrium which the conditions hitherto existing in a given region tend to establish between the numbers of each species, it may be safe to assume that the probability of any new variety establishing itself is but small. But let that equilibrium be disturbed—let some hitherto unknown plants spread widely, as so many European weeds have done in Australia. This must lead to a corresponding diminution in the number of individuals of the previous vegetable inhabitants of the country, and a corresponding reduction among the animals that fed upon them. Let one of these animals be modified so as to be able to derive nourishment from the intrusive species. Is it not evident that the chance of its survival, and that of its similarly modified descendants, would be so great as to approach to certainty, unless the modification happened to bring with it other counterbalancing disadvantages?

JOHN BALL

THE USE AND ABUSE OF COMPLIMENTARY NAMES

THOSE whose fortune it is to work in some particular branch of science which has not been by any means exhausted, and to encounter daily some new form from an unexplored region which seems to warrant recognition as a new species, are often in difficulty to obtain a suitable name, one which shall distinguish the new species from its congeners, or give indication of one of its most prominent characteristics. It would seem that some (I fear many) are not so fully impressed as they should be with the importance of giving appropriate specific names to new species. "Trivial" names is in many cases an accurate designation. When a new name has to be given, it seems to me that the first effort should be directed towards applying a name which has at least some connection with the object to which it is applied, and if possible indicate one of the features by which its specific distinction is established. In very large genera this will often be difficult, but seldom impossible, if sufficient reflection be permitted. This presupposes, of course, clear notions of what are the distinctive features of the new species, and something more than a mere superficial knowledge of its congeners. The custom of giving complimentary names has considerably increased of late years, and seems almost to have culminated in absurdity. It is never a thankful office to impute blame, or point out the failings of others, and I should never have ventured to draw attention to this subject did I not conceive that the application of complimentary specific names has become an abuse which needs to be protested against. I am willing to concede that the occasional dedication of a new species to some acknowledged authority, one who has published a monograph of the genus, or who has identified himself more or

less with the subject, may be a graceful compliment; but even this should hardly supersede a name indicative of some special feature in the new species. My own feelings are in favour of wholly restricting such compliments to generic names. But wherefore should a mere collector, one who has stumbled over a new species by mere accident, by collecting everything that came in his way of a particular kind, unable perhaps even to recognise generic distinctions, be flattered by having his name attached to the new form by some one who has had all the scientific labour in examining, describing, and naming it for him? Has science no higher aim than that of scattering compliments? It must cause many a smile to pass across the countenances of the unscientific if they open a new cryptogamic flora, a monograph, or even glance through a volume of some scientific journal, to see on one page how Mr. Brown ventures to name something new in honour of his friend Mr. Robinson, and a few pages further on Mr. Robinson returns the compliment in favour of Mr. Brown; or in another case how in five or six genera, extending over as many pages, the same "indefatigable collector" is honoured by having his name as many times repeated, as if new species were only so many pegs on which compliments are to be suspended. My own experience is very much restricted to cryptogamic botany, and my remarks may be much less pertinent to other branches of natural science. Zoologists may not be addicted to such forms of flattery. Continental mycologists are certainly very great sinners in this respect. My object in drawing the attention of readers of NATURE to this subject is to protest against this "abuse of complimentary names," and to ascertain if some definite restriction cannot be placed upon this tendency to encumber our lists with an array of names which convey only one meaning, and which I would designate "flattery names." I hardly think it necessary to cite particular instances, as a question of this kind should be decided upon its merits, and without the introduction of personalities. The sceptical should make the experiment with some recent volume containing descriptions of new species. In one contingency, I think that it is not only admissible but advisable to use a complimentary name. If an author describes a species under a name which has already been adopted in the same genus, it would be very inconvenient to have the one specific name applied by two authors to different things. In such a case it is the custom for any one who may be working up and publishing a synopsis of the genus to suppress the most recent of the two specific names, and apply to it the name of the author who unconsciously fell into the error. Provided always that he recognises the species having priority of name as a valid member of the genus, there cannot be much abuse of this recognised practice, against which I have nothing to urge. It would be simple folly to make laws which there is no power but "common sense" to enforce; and no decision which I may determine upon will be binding upon any one save myself; yet I cannot but regret that any who have laboured year after year in love for their own special branch of science, often following it for its own sake alone, through many sacrifices, should be tempted to employ the knowledge they have so acquired as a means whereby to compliment their friends or flatter their inferiors, forgetful of the practical sarcasms that they are hurling at their own pursuits.

M. C. C.

THE ECLIPSE OBSERVATIONS AT BEKUL

THE illustrations which accompany this, for the loan of which we are indebted to the courtesy of the Editor of the *Illustrated London News*, are from photographs of the Eclipse party stationed at Bekul, taken by Mr. McC. Webster, the Collector of South Canara. The first represents the fort in which Mr. Lockyer and Captain

WAITING FOR THE ECLIPSE

THE BUNGALOW AT BEKUL, CANARA

Maclear had erected their instruments. Mr. Davis's photographic and Dr. Thomson's polariscopic observations being carried on at a little distance below. The instruments represented are the η reflector constructed by Mr. Browning, with a mounting by Cooke, and the double refractor, consisting of two telescopes of six inches aperture, mounted on one of the universal stands prepared for the Transit of Venus observations in 1874, and lent by the Astronomer Royal.

The second is a representation of the bungalow which formed the residence of the same party during their stay in India, erected under the friendly shelter of a grove of spreading banyan-trees. The temperature in the middle of the day at Canara reaching commonly to 90° Fahr. within doors, it will be seen how necessary was not only the shelter of the trees for their residence, but the umbrella which a native attendant is holding over the head of one of the observers during the actual time of observation.

ON THE INFLUENCE OF VIOLET LIGHT ON THE GROWTH OF VINES, AND ON THE DEVELOPMENT OF PIGS AND BULLS

GENERAL A. J. PLEASANTON, from Philadelphia, U.S., has been engaged since 1861 with some very interesting experiments on the influence of light, transmitted through violet glass, in developing animal and vegetable life. In April 1861, cuttings of vines of some twenty varieties of grapes, each one year old, of the thickness of a pipe-stem, and cut close to the spots containing them, were planted in the borders inside and outside of the grapery, on the roof of which every eighth row of glass was violet-coloured, alternating the rows on the opposite sides. Very soon the vines began to attract great notice from the rapid growth they were making. Every day the gardener was kept busy in tying up the new wood which the day before had not been observed. In a few weeks after the vines had been planted, the walls and inside of the roof were closely covered with the most luxurious and healthy development of foliage and wood.

In September of the same year Mr. Robert Buist, a noted seedsman and horticulturist, from whom the General had procured the vines, visited the grapery. After examining it very carefully, he said:—"I have been cultivating plants and vines of various kinds for the last forty years; I have seen some of the best vineries and conservatories in England and Scotland; but I have never seen anything like this growth." He then measured some of the vines, and found them forty-five feet in length, and an inch in diameter at the distance of one foot above the ground. And these dimensions were the growth of only five months!

In March 1862 they were started to grow, having been pruned and cleaned in January of that year. The growth in this second season was, if anything, more remarkable than it had been in the previous year. Besides the formation of the new wood, and the display of the most luxuriant foliage, there was a wonderful number of bunches of grapes, which soon assumed the most remarkable proportions—the bunches being of extraordinary magnitude, and the grapes of unusual size and development.

In September, when the grapes were beginning to colour and to ripen rapidly, Mr. Buist visited the grapery again, and estimated that there were 1,200 pounds of grapes. General Pleasanton remarks that in grape-growing countries, where grapes have been grown for centuries, a period of time of from five to six years will elapse before a single bunch of grapes can be produced from a young vine; while here, only seventeen months after, his grapery had yielded the finest and choicest varieties of grapes.

During the next season (1863) the vines again fruited, and matured a crop of grapes, estimated, by comparison

with the yield of the previous year, to weigh about two tons; the vines were perfectly healthy, and free from the usual maladies which affect the grape. Many cultivators said that such excessive crops would exhaust the vines, and that the following year there would be no fruit; as it was well known that all plants required rest after yielding large crops. Notwithstanding, new wood was formed this year for the next year's crop, which turned out to be quite as large as it had been in the season of 1863; and so on, year by year, the vines have continued to bear large crops of fine fruit without intermission for the last nine years. They are now healthy and strong, and as yet show no signs of decrepitude or exhaustion.

The success of the grapery induced General Pleasanton to make an experiment with animal life. In the autumn of 1869 he built a piggery, and introduced into the roof and three sides of it violet-coloured and white glass in equal proportions—half of each kind. Separating a recent litter of Chester country pigs into two parties, he placed three sows and one barrow pig in the white pen, and three other sows and one other barrow pig in the pen under the violet glass. The pigs were all about two months old. It will be observed that each of the pigs under the violet glass was lighter in weight than the lightest pig of those under the sun-light alone in the white pen. The two sets were treated exactly alike; fed with the same kinds of food, at equal intervals of time, and with equal quantities by measure at each meal, and were attended by the same man. On the 4th of May, 1870, the six sows, being weighed, the following conclusion was obtained:—

	Under the violet pens.	Under the white pens.
November 3, 1869	122 lbs.	144 lbs.
March 4, 1870	520 lbs.	530 lbs.
Increase...	398 lbs.	386 lbs.

Consequently, although the pigs placed under the violet pens actually weighed 10 lbs. less than those under the white pens; yet, taking into consideration the 22 lbs. less which the first pigs had previously weighed, there is an actual gain of 12 lbs. The two other barrow pigs offered nearly the same result.

The next experiment of General Pleasanton was with an Alderney bull calf, born on Jan. 26, 1870. At its birth it was so puny and feeble that the man who attends upon his stock—a very experienced hand—told him that it would not live. He directed him to put it in one of the pens under the violet glass. In 24 hours a very sensible change had occurred in the animal. It had arisen on its feet, walked about the pen, took its food freely by the finger, and manifested great vivacity. In a few days his feeble condition had entirely disappeared. It began to grow, and its development was marvellous. On March 31, 1870, two months and five days after its birth, its rapid growth was so apparent that, as its hind quarter was then growing, he had it measured. Fifty days afterwards it had gained six inches in height, carrying its lateral development with it. The calf was turned into the barn yard, and manifested every symptom of full masculine vigour, though at the time he was only four months old. He is now one of the best developed animals that can be found anywhere.

This is only a very short *résumé* of the third edition of a pamphlet published by General Pleasanton, entitled, "On the Influence of the Blue Colour of the Sky in Developing Animal and Vegetable Life: as Illustrated in the Experiments of the Author between the years 1861 and 1871" (Philadelphia, 1871). 8vo. 24 pp.

The account of it which I had addressed to the French Academy was followed by two different notes from Cailletet and Bert. In my next article I will examine them, with some references to the explanation of General Pleasanton's experiments.

Paris, Jan. 10

ANDRÉ POËY

MAGNETIC DISTURBANCES DURING THE LATE TOTAL ECLIPSE

IN the list of papers read before the Paris Academy of Sciences, which was given in last week's *NATURE*, I noticed one on the magnetic perturbations observed at Alençon during the late total eclipse. Now it would at first sight appear reasonable to expect that any effect produced on the magnetic needle at Alençon by a phenomenon whose maximum phase was as far removed as India or Australia, should have nearly equal effect on the needle in England, and in all countries adjoining France. It has moreover been established by frequent comparisons of carefully measured photographic records, taken at different magnetic observatories, that any disturbance of the earth's magnetic force is felt almost simultaneously at stations differing several hundred miles in both latitude and longitude. I was, therefore, justified in supposing that I should find some indications on our photo-magnetic records of a disturbance corresponding to the perturbations of the needle at Alençon, alluded to by M. Lion in his note to the Academy. The result of my examination of the records is, that there is not the slightest trace of a disturbance on either the vertical or horizontal curves, and that the declination magnet has been more than usually quiet, although on the two previous days it happened to have been somewhat disturbed about the hour at which the totality of December 11 occurred.

Accidental causes influence too largely the readings of a declination magnet for much reliance to be placed on them, however careful the observer, when they are in open contradiction to the photo-records of instruments whose diurnal corrections are sensibly constant.

Stonyhurst Observatory, Jan. 28

S. J. PERRY

SCHOLARSHIPS AND EXHIBITIONS FOR NATURAL SCIENCE IN CAMBRIDGE, 1872

THE following is a list of the Scholarships and Exhibitions for proficiency in Natural Science to be offered in Cambridge during the present year:—

TRINITY COLLEGE.—One or two of the value of about 80*l.* per annum. The examination will be on April 5, and will be open to all undergraduates of Cambridge and Oxford, and to persons under twenty who are not members of the Universities. Further information may be obtained from the Rev. E. Blore, Tutor of Trinity College.

ST. JOHN'S COLLEGE.—One of the value of 50*l.* per annum. The examination (in Chemistry, Physics, and Physiology, with Geology, Anatomy, and Botany) will be on the 12th of April, and will be open to all persons who are not entered at the University, as well to all who have entered and have not completed one term of residence. Natural Science is made one of the subjects of the annual College Examination of its students at the end of its academical year, in May; and Exhibitions and Foundation Scholarships will be awarded to students who show an amount of knowledge equivalent to that which in Classics or Mathematics usually gains an Exhibition or Scholarship in the College. In short, Natural Science is on the same footing with Classics and Mathematics, both as regards teaching and rewards.

CHRIST'S COLLEGE.—One or more, in value from 30*l.* to 70*l.*, according to the number and merits of the candidates, tenable for three-and-a-half years, and for three years longer by those who reside during that period at the College. The examination will be on March 19, and will be open to the undergraduates of this College; to non-collegiate undergraduates of Cambridge; to all undergraduates of Oxford; and to any students who are not members of either University. The candidates may select their own subjects for examination. There are

other Exhibitions which are distributed annually among the most deserving students of the College.

CAIUS COLLEGE.—One of the value of 60*l.* per annum. The examination will be on March 19 in Chemistry and Experimental Physics, Zoology with Comparative Anatomy and Physiology, and Botany with Vegetable Anatomy and Physiology; it will be open to students who have not commenced residence in the University. There is no limitation as to age.—Scholarships of the value of 20*l.* each, or more if the candidates are unusually good, are offered for Anatomy and Physiology to members of the College.—Gentlemen elected to the Tancred Medical Studentships are required to enter at this College; these Studentships are four in number, and the annual value of each is 113*l.* Information respecting these may be obtained from Mr. B. J. L. Frere, 28, Lincoln's Inn Fields, London.

CLARE COLLEGE.—One or more of the value of 50*l.* per annum. The examination (in Chemistry, Chemical Physics, Comparative Anatomy and Physiology, and Geology) will be on March 19, and will be open to students intending to begin residence in October.

DOWNING COLLEGE.—One or more of the value of 40*l.* per annum. The examination (in Chemistry, Comparative Anatomy, and Physiology) will be early in April, and will be open to all students not members of the University, as well as to all undergraduates in their first term.

SIDNEY COLLEGE.—Two of the value of 40*l.* per annum. The examination (in Heat, Electricity, Chemistry, Geology, Physiology, Botany) will be in October, and will be open to all students who may enter on the College boards before October 1.

EMMANUEL COLLEGE.—One or more of the value of 40*l.* to 60*l.* per annum. The examination on March 19 will be open to students who have not commenced residence.

PEMBROKE COLLEGE.—One or more of the value of 20*l.* to 60*l.*, according to merit. The examination in June (in Chemistry, Physics, and other subjects), will be open to students under twenty years of age.

ST. PETER'S COLLEGE.—One from 50*l.* to 80*l.* per annum, according to merit. The examination, on April 4 (in Chemistry, Comparative Anatomy and Physiology, and Botany), will be open to students who will be under twenty-one years of age on October 1, 1872, and who have not commenced residence.

Although several subjects for examination are in each instance given, this is rather to afford the option of one or more to the candidates than to induce them to present a superficial knowledge of several. Indeed, it is expressly stated by some of the Colleges that good clear knowledge of one or two subjects will be more esteemed than a general knowledge of several.

Candidates, especially those who are not members of the University, will, in most instances, be required to show a fair knowledge of Classics and Mathematics, such, for example, as would enable them to pass the Previous Examination.

There is no restriction on the ground of religious denomination in the case of these or of any of the Scholarships or Exhibitions in the Colleges or in the University. Further information may be obtained from the tutors of the respective Colleges.

It may be added that Trinity College will give a Fellowship for Natural Science once, at least, in three years; and that most of the Colleges are understood to be willing to award Fellowships for merit in Natural Science equivalent to that for which they are in the habit of giving them for Classics and Mathematics.

The following lectures in Natural Sciences will be delivered at Trinity, St. John's, and Sidney Sussex Colleges during Lent Term, 1872:—

On Sound and Light. (For the Natural Sciences Tripos.) By Mr. Trotter, Trinity College, on Mondays, Wednesdays, and Fridays, at 10, commencing Monday, February 5.

On Electricity and Magnetism. (For the Natural Sciences Tripos, a short course in continuation of that of last term.) By Mr. Trotter, Trinity College, on Tuesdays and Thursdays, at 9, commencing Thursday, February 1.

On Electricity and Magnetism, for the special examination for the ordinary degree. By Mr. Trotter, Trinity College, on Tuesdays, Thursdays, and Saturdays, at 11, commencing Thursday, February 1.

On Chemistry. By Mr. Main, St. John's College, on Mondays, Wednesdays, and Fridays, at 12, in St. John's College laboratory, commencing Wednesday, January 31. Instruction in Practical Chemistry will also be given.

On Palæontology. (The Annuloida, &c.) By Mr. Bonney, St. John's College, on Mondays, Wednesdays, and Fridays, at 9, commencing Wednesday, January 31.

On Geology. (For the Natural Sciences Tripos. Physical Geology.) By Mr. Bonney, St. John's College, on Tuesdays and Thursdays, at 10, commencing Thursday, February 1.

A course on Stratigraphical Geology will be given in the Easter Term. Papers will be given every Saturday at 11.

Elementary Geology (for the special examination), on Tuesdays and Thursdays, at 11, commencing Thursday, February 6.

On Botany. (For the Natural Sciences Tripos.) By Mr. Hicks, Sidney College, on Tuesdays, Thursdays, and Saturdays, at 12, beginning on Thursday, February 1. The lectures during this term will be on Structural and Physiological Botany.

On the Physiology of the Nervous System. By the Trinity Pælector in Physiology (Dr. M. Foster), at the New Museums, on Mondays, Tuesdays, and Wednesdays, at 11, commencing Monday, February 5.

The Physiological Laboratory is also open for practical instruction in Physiology to all those who have gone through the elementary course.

NATURAL SCIENCE AT OXFORD

THE following regulations have been issued for the Final Honour Examination in the Natural Science School:—

BIOLOGY.—1. Candidates who offer themselves in the Final Honour Examination for examination in Biology will be expected to show an acquaintance, firstly, with General and Comparative Anatomy; secondly, with Human and Comparative Physiology, inclusive of Physiological Chemistry; and thirdly, with the General Philosophy of the subject.

2. In these subjects the candidates will be examined both by paper work and practically; and will be required to give evidence of being competent not merely to verify and describe specimens already prepared for naked-eye or microscopic demonstration as the case may be, but also to prepare such or similar specimens themselves.

3. The following works are provisionally recommended by the Board of Studies for use in the study of the above-mentioned Departments of Biology. When the letter F or G is prefixed to the title of a work, it will be understood to indicate that the work is written in French or German, and is not as yet translated into English:—

General Anatomy.—Sharpey in Quain's *Anatomy*, ed. 7, 1867; The Micrographic Dictionary, by Griffiths and Henfrey, now in course of re-publication; The Histological Catalogue of the College of Surgeons, by Prof. Quekett; (G) Kölliker's *Handbuch der Gewebelehre*, ed. 1867; Stricker's *Handbook of Human and Comparative*

Histology, now in course of translation for the New Sydenham Society.

Comparative Anatomy.—Huxley's Introduction to the Classification of Animals; Huxley's *Anatomy of Vertebrated Animals*, 1871; (F) and (G) Gegenbaur's *Grundzüge der Vergl. Anatomie*, 1869; (F) Milne-Edwards, *Leçons sur la Physiologie*, 1857-1870; The Osteological and Physiological Catalogues of the College of Surgeons, by Prof. Owen; The Anatomical and Physiological Catalogues of the Oxford Museum; Flower's *Osteology of Mammalia*, 1871; (F) Cuvier's *Ossements Fossiles*, ed. 2, 1821-1824; Rolleston's *Forms of Animal Life*, 1870; Bronn's *Klassen und Ordnungen des Thierreichs*, 1860-1871.

Human Physiology.—Carpenter's *Human Physiology*, ed. 7, 1869; (G) Funke's *Lehrbuch der Physiologie*, now in course of re-publication; (G) Hermann's *Handbuch der Biologie*, 1870; Dalton's *Human Physiology*; Draper's *Human Physiology*, 1856; (G) Ranke, *Grundzüge der Physiologie*, 1868; (G) Wundt's *Lehrbuch der Physiologie*, 1865; (G) Ludwig's *Lehrbuch der Physiologie*, 1858-1861; (G) Budge's *Lehrbuch der speciellen Physiologie des Menschen*, 1862.

Comparative Physiology.—Carpenter's *Comparative Physiology*, 1854; Marshall's *Outlines of Physiology*, 1867; (F) Milne-Edwards' *Leçons sur la Physiologie*; (G) Bergmann and Leuckart, *Anatomisch-physiologische Uebersicht des Thierreichs*, 1855.

General Philosophy of Biology.—a. Darwin's *Origin of Species*; Van der Hoeven's *Philosophia Zoologica*, 1864; Lyell's *Principles of Geology*, ed. 1870, chaps. xxxiv—xxxvii; Mivart's *Genesis of Species*; Spencer's *Principles of Biology*, 1864-1867; *Principles of Psychology*, ed. 1868-1871; b. Agassiz's *Essay on Classification*, chap. iii.; Whewell's *History of the Inductive Sciences* (For a Historical Survey of the Progress of Biology); c. Van der Hoeven's *Handbook of Zoology*, 1857; Nicholson's *Manual of Zoology*, ed. 2, 1871 (For Zoology); Van der Hoeven's *Philosophia Zoologica*, lib. iv.; Lyell's *Principles of Geology*, chap. xxxviii—xli. (For Geographical Distribution).

Ethnology and Anthropology.—Waitz's *Anthropology*; Brace's *Races of the Old World*, ed. 2, 1870.

4. Candidates may, in addition to the amount of work indicated in the preceding paragraphs, bring up any of the "Special Subjects" contained in the list appended below. A candidate who offers himself for examination in a special subject will be expected to show, firstly, a detailed practical acquaintance with specimens illustrating that subject, for which purpose the catalogues in the University Museum can be made available; and, secondly, exact knowledge of some one or more monographs treating of it. Excellence, however, in a special subject will not compensate for failure in any essential part of the general examination. Every candidate must state, at the time of entering his name for examination, what special subject, if any, he takes in. List of special subjects and of books recommended in connection with them:—

Comparative Osteology.—Cuvier's *Ossements Fossiles*, any one of the five volumes; Flower's *Osteology of Mammalia*; Prof. Huxley's *Anatomy of Vertebrated Animals*.

The Comparative Anatomy and Physiology of the Organs of Digestion.—The Physiological Catalogue of the Royal College of Surgeons, vol. i.; (F) Milne-Edwards's *Leçons*, vol. vi.; Articles "Stomach and Intestine" and "Pancreas" in Todd's "Cyclopædia of Anatomy and Physiology;" (F) Schiff, *Leçons sur la Physiologie de la Digestion*, 1868.

The Comparative Anatomy and Physiology of the Organs of Circulation and Respiration.—(F) Milne-Edwards's *Leçons sur la Physiologie*, vol. iii.; (F) Marey's *Physiologie Médicale de la Circulation du Sang*, 1863; (F) Bert, *Leçons sur la Physiologie Comparée de la Respiration*, 1870.

The Comparative Anatomy and Physiology of the Nervous System.—(F) Leuret's and Gratiolet's *Anatomie Comparée du Système Nerveux*, Tom. ii., par M. Pierre Gratiolet, 1857; (F) Vulpian's *Leçons sur le Système Nerveux*; Brown-Séquard's *Lectures*, 1865.

The Comparative Anatomy and Physiology of the Reproductive Systems.—Physiological Catalogue of the Royal College of Surgeons, vols. iv. and v.; (G) Kölliker's *Entwicklungsgeschichte*, 1861; (F) Milne-Edwards *Leçons*, vol. ix.

Ethnology.—Brace's *Races of the Old World*, ed. 2, 1870.

5. Candidates who offer themselves for examination in Geology, Zoology, or Botany will be required to exhibit practical acquaintance with those subjects to at least the same extent as candidates who offer themselves for examination in any one of the special subjects above mentioned are required to do with reference to those subjects. But they will not be required to go through the same amount of practical work in the departments of Biology not specially connected with Geology, Zoology, or Botany as candidates who do not bring up any one of these three subjects.

NOTES.

THE Senior Wrangler for the present year is Mr. Robert Rumsey Webb, son of the late Mr. Thomas Webb, of Monmouth. He was educated under the Rev. C. M. Roberts, M.A. (St. John's College, Cambridge), at the Monmouth Grammar School, and entered at St. John's College in October 1868, having previously obtained a Somerset Exhibition by open competition. Mr. Webb's college tutor was Mr. J. E. Sandys; his private tutor Mr. Routh, of St. Peter's. Mr. Horace Lamb, the Second Wrangler, was born at Stockport, in November 1849, was educated at the Stockport Grammar School, and for a short time studied at Owens College, Manchester. In the year 1868 he gained a minor scholarship at Trinity College, and in 1870 was elected to a Foundation Scholarship. He was placed in the first class in the First B.A. Mathematical Honour Examination in the University of London in 1870; and in the succeeding year gained the Sheepshanks Astronomical Exhibition at Trinity College. His college tutor was Mr. Prior; private tutor, Mr. Routh, of St. Peter's. Mr. John Bascombe Lock, the Third Wrangler, son of Mr. Joseph Lock, of Dorchester, was educated at the Bristol Grammar School. In the Easter Term of 1868 he obtained an open Mathematical Scholarship at Caius College, where he obtained a Foundation Scholarship in May. Mr. Routh was his private tutor, and Mr. N. M. Ferrers his college tutor.

THE following are the lectures on Science at the University of Oxford this term:—The Rev. Bartholomew Price, the Siedleian Professor of Natural Philosophy, on Light; the Savilian Professor of Astronomy, Rev. C. Pritchard, on Newton's "Principia" and the Lunar Theory; Prof. Clifton, Professor of Experimental Philosophy, on Experimental Optics; Prof. Westwood, Professor of Zoology, on the Classes and Orders of Articulated Animals; Prof. Phillips, Professor of Geology, on the Geology of the country round Oxford; Prof. Rolleston, Professor of Anatomy, on Digestion. In addition to these lectures Prof. Clifton announces that the physical laboratory of the University will be open daily for instruction in Practical Physics from 10 to 4 o'clock each day. Prof. Rolleston proposes to form classes for practical instruction as in former Terms. The Chemical Laboratory is open as usual for Quantitative and Qualitative analysis. Dr. Acland, the Regius Professor of Medicine, also announces that, in addition to his course of clinical instruction at the infirmary, he "will also on days and places to be hereafter

mentioned demonstrate on the spot sanitary defects in a town and in a village, illustrating thereon principles of general and special sanitary administration." In the Laboratory of the Medical Department at the University Museum various methods of examining water and other subjects connected with sanitary science will be taught, commencing on February 1, by Mr. C. C. Pöde, M.B., Exeter College, with the assistance of Mr. S. J. Sharkey, B.A., of Jesus College. Those lectures and demonstrations, on sanitary matters are a novel and peculiarly-interesting feature introduced this Term for the first time.

DR. PAGET has been appointed Regius Professor of Medicine at the University of Cambridge.

THE Professorship of Botany in the Royal College of Science for Ireland is vacant by the resignation of Prof. W. T. Thistelton-Dyer.

THE King of Italy has conferred upon Mr. Edward Whymper, Vice-President of the Alpine Club, the decoration of Chevalier of the Order of St. Maurice et Lazare, "in recognition of the value of his recently published magnificent work upon the Alps."

WE have to record the death, on Saturday last, of Dr. W. Baird, F.R.S., of the Zoological Department of the British Museum, at the age of 69.

THE American Academy of Arts and Sciences on the 9th of January presented the American Rumford Medals to Mr. J. Harrison, jun., of Philadelphia, for his invention of safety boilers. The medals are provided for by an endowment fund or gift of 5,000 dols. in the United States Funds, to the Academy, made by Count Rumford in 1796. By the conditions of this endowment the interest of the fund is to be applied "every second year" to the procuring of two medals, one of gold and one of silver, in value equal to the amount of two years' interest of the fund (600 dols.), and these medals (or their equivalent in money) are to be awarded to the author of the most important discovery or useful improvement in the application of heat or light, which shall, in the opinion of the Academy, "tend most to promote the good of mankind." Although the fund was provided at that early day no discovery or improvement of sufficient importance, in the opinion of the Academy, appeared until 1859, when the first award was made to Dr. Robert Hare, of Philadelphia, for his compound oxy-hydrogen blowpipe and improvements in galvanic apparatus. Since then the awards of the medal have been as follows:—1862, John B. Ericsson, for his caloric engine; 1865, Prof. Daniel Treadwell (Harvard College), for improvements in the management of heat; 1867, Alvan Clark, for improvement in lens of refracting telescope; 1870, George H. Corliss, Providence, for improvements in the steam-engine; 1871, Joseph Harrison, jun., Philadelphia, for "the mode of constructing steam boilers invented and perfected by him," which "secures great safety in the use of high-pressure steam, and is, therefore an important improvement in the application of heat."

A MEETING in aid of the Livingstone Exploration Fund was held in the City of London on Tuesday last, the Lord Mayor in the chair; the subscriptions received in the room amounting to over 250/. Sir H. Rawlinson announced at the meeting that he had that day received from the Foreign Office a despatch which was to be presented by Lieutenant Llewellyn Dawson to the Government agent at Zanzibar, in which Dr. Kirk was instructed to give to Lieutenant Dawson all the advice and assistance in his power, and was authorised to advance any sum which might be required for the purposes of the expedition within the limit of the balance of the Government grant of 1,000/, which remained in his hands, and which, according to the last account, amounted to 650/. He also stated that the subscriptions already received reached 2,700/, or 2,800/.

THE Second Course of Cantor Lectures for the session will be delivered by the Rev. Arthur Rigg, M.A., on "Mechanism." The first lecture will be given on Monday evening, Feb. 5, at eight o'clock, and the remainder on following Mondays till March 11.

THE *Athenæum* states that Mr. E. J. Reed, C.B., late Chief Constructor of the Navy, is about to establish a new quarterly magazine of a scientific character, the first number of which will appear early in March, to be devoted to the improvement of naval architecture, marine engineering, steam navigation, and seamanship generally. It will be called *Naval Science*, and will be under the joint editorship of the Rev. Dr. Woolley, Director of Education to the Admiralty, and Mr. Reed.

THE following are the number of entries for the classes at the Newcastle College of Physical Science for the present term:—Evening classes—chemistry, 36 (including one lady); physics, 40 (including four ladies); geology, 19; advanced mathematics, 15; elementary mathematics, 24; political economy, 12 (this class will not be held). Day classes. New entries at Epiphany term—chemistry, 8; physics, 7; mathematics, 8; geology, 3.

THE following are appointed trustees to the Alder Memorial Fund, of which we spoke last week:—Sir W. G. Armstrong, Mr. L. L. Bell, Mr. J. Blacklock, Mr. H. B. Brady, Mr. A. Hancock, Mr. D. P. Morison, Mr. R. S. Newall, and the Rev. A. M. Norman; who have received the following suggestion from the subscribers:—"That it should be suggested to the trustees that the establishment of a College of Physical Science in Newcastle appears to offer opportunities for the employment of the fund in furtherance of zoological science, more likely to be generally appreciated as a memorial of our late distinguished naturalist than the scheme originally proposed, and that in the event of the establishment of a chair of biology in the College, the application of the interest of the fund might properly take the form of a scholarship or other reward for proficiency in zoology, to be associated with Mr. Alder's name."

THE Natural History Society of Newcastle-on-Tyne has received a gift of 20l. from the Misses Bewick; which sum is to be applied in defraying the cost of new cabinets as they might be required. The Society has also been presented with a most valuable collection of fossils from Mr. M. R. Pryor, Fellow of Trinity College, Cambridge, consisting of about 140 species of Upper Greensand fossils from Cambridgeshire; 130 species from the Red Crag; a fine series from the Lower Greensand Coprolite Bed of the Eastern Counties; a fair representative collection from the Oxford Clay at St. Ives, Huntingdon; and a number of Chalk fossils; all admirably mounted and named.

A RESOLUTION has been presented to the Congress of the United States providing for the printing of a number of copies of the report of the investigation by Prof. Hayden upon the geology of Nebraska and Wyoming territory.

IN a letter from Government House, Barbadoes, January 6, 1872, to one of our contributors, the Hon. Rawson Rawson writes:—"Agassiz, Count Pourtales, and a party of savans have just left this. The United States surveying vessel in which they go to the Pacific had to put in for some slight repairs. They were here for two days and I went on board and spent one day with them. Agassiz pronounced my collection of shells quite unique in series of specimens, from the youngest stage to adult. He was in ecstasies with the *Holopus*,* which he spent hours in examining, and I had to let him take it away to describe it in all detail. He had seen and studied D'Orbigny's *H. rangii*, and thinks mine the same species, but that it is of the normal form, while the one D'Orbigny

described was both incomplete and abnormal. I had Dr. Gray's sketch with me, and certainly the resemblance to it was very great. I think I may fairly regard it as the gem of my collection; but in writing of it I must not forget to tell you of our day's dredging. It was successful beyond our expectations—four live specimens of a fine new crinoid, like *Apicrinus*, which Agassiz was able to watch alive for hours; a *Pleuronomaria Quoyana*, of which the artist was able to draw the animal; a new and wonderfully beautiful species of *Latissia*, Brachiopods in any number, vitreous sponges in mass, some new Echini. You can fancy the state Agassiz was in, and time would quite fail me to tell you of all the interesting things he said about the various forms as he recognised them. Need I say that all this has determined me to make an effort to get our shores dredged, beginning in shallow and going out to the depth they dredged at, i.e., about forty or fifty fathoms. We shall, doubtless, get lots of treasures, upon the duplicates of which you shall have first claim."

PROF. B. A. GOULD writes from the Argentine National Observatory at Cordoba, under date December 8, 1871, that the new observatory had then been formally inaugurated about six weeks, after a series of most unexpected and vexatious obstacles and delays. The climate had, however, proved far less propitious than had been expected, the cloudy nights being nearly as numerous as the clear ones, although no rain falls during one half the year. When, however, the sky is clear, it is of a wondrous transparency, stars of the seventh magnitude being distinctly visible on favourable nights to the naked eye, and the planets magnificent in their brilliancy. The large equatorial was already in adjustment, and Prof. Gould had had some beautiful views of Saturn. Owing to the breaking out of the epidemic in Buenos Aires at the beginning of 1871, all communication with Europe, by post or otherwise, had been almost entirely suspended during the year; faint rumours of the success of the eclipse observations in Spain in December 1870 had but just reached Cordoba.

A BLACK marble slab, bearing the following inscription in brass characters, has just been placed over the grave of the late Sir John Herschel, in the north aisle of the nave of Westminster Abbey:—

JOHANNES HERSCHEL
GULIELMI HERSCHEL
NATU OPERE FAMA
FILII UNICUS
"CÆLUS EXPLORATIS"
HIC PROF. NEWTONUM
RQUESCIT
GENERATIO ET GENERATIO
MIRACULA DEI NARRABUNT
PSALM. CXLV. 4, 5.
VIXIT LXXXI. ANNOS
OBIT UNDICESIMO DIE MAII
A. D. MDCCCLXXI.

THE following account of the fall of a meteorite is taken from Gruithuysen's "Naturgeschichte des Gestirns Himmels:—"On July 24, 1799, at 10.30 P.M. a fiery globe larger and brighter than the full moon, as seen from Mornes, passed from S. to N. in 2 s., and burst leaving a white cloud. 3 m. after explosion the two observers heard a heavy thunder-clap that shook the windows and opened some of them. The 15 leagues distant chain of the Pyrenees gave a continuous echo lasting 4 s. The fragments fell in extraordinary quantity between Juliac and Barboian, 4 hours N. and 5 hours NE. from Mornes; they fell fused so as to bake the impression of straw, and make no sound on the roof of houses, weighing 4 "loth" to 20 "pfund." The bill of fire was seen from Bayonne, Auch, Pau, Tanbes, Bordeaux, and Toulouse, from the latter place only as something larger than a fixed star.

WE give a fuller account of the volcanic eruption at Ternate

* Vide Notes on *Holopus*. By Dr. J. E. Gray. Annals and Mag. Nat. Hist., vol. viii., 4th series, p. 394.

alluded to by our correspondent Mr. A. B. Meyer in *NATURE* for January 18. The *Batavia Handelsblad* of Sept. 25 states that on the afternoon of Aug. 7 a violent earthquake was felt, of which the exact direction was unknown. The Ternate mountain had from 9 A.M. caused a dull, rumbling sound to be heard, varied at intervals by loud reports, and began in the course of the day to cast out streams of lava. The sky looked dark, and the whole country round about was darkened by the down-coming clouds of smoke. Luckily a southerly wind sprung up, which gave another direction to the glowing lava-streams flowing landwards, and led the fire in seven currents to the ravines. This frightful natural phenomenon held on during the night between the 7th and the 8th. The inhabitants, thinking their island to be doomed, could not sleep, and passed the night outside their houses looking up anxiously at the furious volcano which seemed to threaten them all with certain destruction. At day-break the outburst became still worse, and the population began to fly to the islands of Tidore and Halmahera. The eruption of fire and stones held on for about twelve days, after which it became less. The damage done to houses and plantations is enormous, but has not as yet been accurately ascertained. This outburst was the most violent known at Ternate within the memory of man. The whole island shook from the underground motion. A moment of rest was followed by another explosion, which shook the houses to their foundations. There were, luckily, only some slight earthquake-shocks felt. On Aug. 28 the volcano was again at rest, at least, only a small cloud was seen coming out of the crater.

We take the following from the *Times of India*:—"The *Western Star*, which is *par excellence*, the journal for marvels, tells the following story of a murder:—"The manner in which the murderers were detected would, our contemporary adds, if true, go far to prove the Darwinian theory. The story briefly told is this: A Madrassee had a monkey which he was very fond of. The man had occasion to go on a journey, and took with him money and jewels, and his chum the monkey. Some rogues determined to rob him of everything he had; and accordingly they lay in wait for him and murdered him. Having secured the money and jewels they threw the murdered man into a dry well, and having covered it up with twigs and dry leaves, they went home. The monkey, who was on the top of a tree, saw the whole of the proceedings, and when the murderers departed he came down and made tracks for the Tahsildar's house, and by his cries and moans attracted the attention of that functionary. Inviting the Tahsildar by dumb signs to follow him, the monkey went to the well and pointed downwards. The Tahsildar thereupon got men to go down, and of course the body was discovered. The monkey then led the men to the place where the jewels and money were buried. He then took them to the bazaars, and as soon as he caught sight of one of the murderers he ran after him, bit him in the leg, and would not let him go till he was secured. In this way all the murderers were caught. The men, it is said, have confessed their crime, and they now stand committed for trial before the Tellicherry Court at the ensuing session. That monkey, we think, ought to be made an inspector of the police."

THE Panama papers report an increasing demand for the Colombian gaucha, and urge the Government to the enactment of regulations to prevent the entire destruction of the forests of these trees in Darien, where they are most abundant. Instead of simply treating the trees for the juice, as the maples are managed in the United States, the tree is cut down, and, of course, no further benefit can be derived from it. In illustration of the extent to which this vegetable product is now being collected, the *Panama Star* and *Herald* informs us that 160 tons had just been brought to that city as the cargo of a single vessel, mostly from the vicinity of Guayaquil.

SCIENTIFIC SERIALS

THE *Scottish Naturalist* for January.—This number is mainly occupied by a number of short papers illustrative of various subjects of interest or novelty in the natural history of Scotland, among which we may notice especially the British species of *Crambus*, a genus of moths, by the Editor; on the Cachalot or Sperm-whale (*Physeter macrocephalus*) of the north-east of Scotland, by Robt. Walker, with plate; and the commencement of the Editor's "Insecta Scotica," an essay to catalogue the insects inhabiting Scotland, with a map to show the natural divisions of the country into the 12 districts adopted in the list. The introductory remarks to the Editor's catalogue of Lepidoptera are valuable, and the article, when completed, promises to be an important contribution to British zoological literature.

THE *American Journal of Science and Art* for November 1871 opens with a continuation of Prof. Le Conte's elaborate paper on "Some Phenomena of Binocular Vision." Prof. Dana, in an article on the position and height of the elevated plateau in which the glacier of New England in the glacial era, had its origin, considers that the idea of one central glacier source for the whole continent is without foundation. The icy plateau he locates at the watershed between the St. Lawrence valley and Hudson's Bay at an altitude at least 4,500 feet above the present level. With the exception of a preliminary catalogue of the bright lines in the spectrum of the chromosphere, by Prof. C. A. Young, which we propose to reprint, the remaining papers in this number are chiefly chemical, and of varied interest; but of which it would be impossible to give the substance in the form of a brief abstract.

The first article in the December number treats of the geological history of the Gulf of Mexico, and is accompanied by a map, which is, unfortunately, not coloured, and is hence somewhat obscure. The article is divided into three portions, treating respectively of the cretaceous period, the tertiary period, and the quaternary beds. This is followed by an article by Asaph Hall, on the Astronomical Proof of a Resisting Medium in Space. It will be remembered that one of the main proofs of the existence of the interstellar æther is the retardation of Encke's Comet. So long ago as the year 1819 Encke calculated that the periodic times of the comet had diminished to the extent of more than half a day during thirty-three years. Thus the pericæic time between 1786 and 1795 was 1,208.112 days, while between 1805 and 1819 it was 1,207.424; and in order to account for the diminution, Encke adopted the hypothesis of a resisting medium in space. From later observations of this and other comets, Mr. Hall is led to the conclusion that comets furnish no proof of the existence of the æther, and that the retardation of Encke's comet is due to some unknown cause, possibly to the fact of its passing through streams of meteoric matter, which may influence its motion.

—Mr. Southworth gives an account of a new Micrometric Goniometer eye-piece, formed by means of a micrometer capable of measuring to the $\frac{1}{250000}$ of an inch.—Dr. Dawson contributes an article on the bearing of Devonian Botany on questions as to the Origin and Extinction of Species, in which he expresses a hope that the further study of fossil plants may enable us thus to approach to a comprehension of the laws of the creation, as distinguished from those of the continual existence of species. The other articles relate to the American Spongilla, a Craspedote, Flagellate Infusorian, by Professor H. James Clark; description of a Printing Chromograph, by the use of which it has been proved that "for three observers, twice as many observations can be reduced in the same time as when a recording chromograph is employed." The next paper was read before the American Association at Indianapolis, and discusses the longitude determination across the Continent. This embodies results obtained by the Coast Survey, in their endeavours to determine the longitude of San Francisco and various intermediate points by telegraphic exchange of clock signals with the Harvard Observatory.—The remaining papers treat of the Invertebrata dredged in Lake Superior in 1871; and of Kilauwa and Mauna Loa.

In the number for January 1872, the commencement of Vol. iii. of the new series, we find a valuable article on Alpine geology by Prof. Sterry Hunt, in the form of a review of Favre's *Recherches Géologiques*. Mr. John De Laski notices the evidence of glacial action on Mount Katadin, the highest land in Maine, and of the Devonian formation, now 5,000 feet above the sea, the top of which he believes to have been overridden

by the glacier. The total thickness of the glacier he estimates at not less than 8,000 feet, and believes that by the slow grinding motion of this ice-sheet all the surface of New England became broken up to great depths. We have again a number of chemical articles, and an interesting contribution to geology by Mr. C. H. Hitchcock, on the Norian or Upper Laurentian Group of New Hampshire. In this number there is also, as usual, a variety of miscellaneous information on the various branches of physical and natural science.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 25.—“On the Action of Low Temperatures on Supersaturated Solutions of Glauber's Salt.” By Charles Tomlinson, F.R.S.

“On the Elimination of Alcohol.” By A. Dupré, Lecturer on Chemistry at Westminster Hospital. Communicated by W. Odling, F.R.S.—Obviously three results may follow the ingestion of alcohol. All the alcohol may be oxidised and none be eliminated, or a portion only may be oxidised and the rest be eliminated unaltered; or, lastly, all may be eliminated again unaltered. Assuming the last to be the case, it would follow that, if a certain quantity of alcohol be taken daily, the amount eliminated would increase from day to day until, at last, the amount eliminated daily would equal the daily consumption, be this time five, ten, or more days. If, on the other hand, all the alcohol consumed is either oxidised or eliminated within twenty-four hours, no increase in the daily elimination will take place in consequence of the continuance of the alcohol diet. Guided by these considerations the author undertook two series of experiments, in which the amount of alcohol eliminated by both kidneys and lungs was carefully estimated. The analytical processes employed are described in detail. First series:—After a total abstinence from alcohol for eleven days, the urine and breath were examined, after which, from the 12th to the 24th day, both inclusive, the author took 112 cub. centims. of brandy daily (equal to 48·68 grms. absolute alcohol). The urine and breath were examined on the 12th, the 18th, and the 24th day. The urine was also examined during the five days following the cessation of the alcohol diet. The analytical results obtained are given in a table. Second series:—After having again abstained from the use of alcohol in any shape during ten days, the author took 56 cub. centims. of brandy (same as above) at 10 A.M. on March the 29th. The urine was collected from three to three hours up to the 12th, from the 12th to the 24th, and during the next succeeding two days. The alcohol eliminated in the breath was also estimated during the same intervals. The analytical results are also arranged in a tabular form. The results of both series may be summed up as follows:—The amount of alcohol eliminated per day does not increase with the continuance of the alcohol diet; therefore all the alcohol consumed daily must, of necessity, be disposed of daily; and as it certainly is not eliminated within that time, it must be destroyed in the system. The elimination of alcohol following the ingestion of a dose or doses of alcohol ceases in from nine to twenty-four hours after the last dose has been taken. The amount of alcohol eliminated, in both breath and urine, is a minute fraction only of the amount of alcohol taken. In the course of these experiments, the author found that, after six weeks of total abstinence, and even in the case of a teetotaler, a substance is eliminated in the urine, and perhaps also in the breath, which, though apparently not alcohol, gives all the reactions ordinarily used for the detection of traces of alcohol, viz., it passes over with the first portions of the distillate, it yields acetic acid on oxidation, gives the emerald-green reaction with bichromate of potassium and strong sulphuric acid, yields iodoform, and its aqueous solution has a lower specific gravity and a higher vapour tension than pure water. The presence of a substance in human urine and the urine of various animals, which yields iodoform, but is not alcohol, had already been discovered by M. Lieben. The quantity present in urine is, however, so small that the precise nature of this substance has not as yet been determined. Finally, the author points out an apparent connection between this substance and alcohol. It was found that, after the elimination due to the ingestion of alcohol had ceased, the amount of this substance eliminated in a given time at first remained below the quantity normally excreted, and only

gradually rose again to the normal standard. A careful study of this connection may perhaps serve to throw some light upon the physiological action of alcohol.

“The Absolute Direction and Intensity of the Earth's Magnetic Force at Bombay, and its Secular and Annual Variations.” By Mr. Charles Chambers, F.R.S., Superintendent of the Colaba Observatory.—The observations discussed in this paper were taken at the Colaba Observatory during the years 1867 to 1870, and consist of observations of Dip, Declination, and Horizontal Intensity. The principal results deduced by the author from these observations are shown in the following statement:—

Magnetic Element.	Epoch.	Value at epoch.	Value at common epoch, January 1st, 1859.	Secular change. Per annum.	Semiannual inequality. Excess of April to September over mean of year.	Calculated error of a single weekly determination.
Declination	April 1, 1868	0° 46' 47" E.	0° 48' 36" E.	+2 5	+1	± 20
Dip	Oct. 1, 1868	19° 4' 2"	19° 4' 7"	+1 9	+0 3	± 20 35"
Horizontal Force	April 1, 1869	8 9591	8 9581	+ 0040	0000	± 0043"
Total Force	Jan. 1, 1861	8 5844	8 5864	+ 0039	+ 0003	—

In column 2 is entered the mean epoch to which the mean value of each element, entered in column 3, corresponds.

The absolute observations were taken at a height of 38 feet above the ground, and by comparing them with observations taken with differential instruments at a height of 6 feet above the ground, they are shown to indicate distinctly a diminution of terrestrial magnetic action with increase of height, with respect both to secular variation of Declination and Horizontal Force, and to diurnal inequality of Horizontal Force.

Royal Geographical Society, January 22.—Sir H. C. Rawlinson, president, in the chair.—Mr. C. R. Markham, secretary, read, at the request of the president, the following statement regarding the proposed Exhibition for the Search and Relief of Dr. Livingstone.—“Letters were received from Livingstone, dated at Lake Bangweolo, on July 8, 1868, and the last that have come to hand were dated Ujiji, May 30, 1869. He announced that the work still before him was to connect the lakes he had discovered; and he intended to explore a lake to the westward of Tanganyika, in the Manyema country, and thence to complete his labours, but he was sorely in need of men and supplies. The Arab traders interested in the slave-trade were anxious to thwart him, and no one would take charge of his letters. He mentioned having written thirty-four letters which had been lost. This is the last positive news from Dr. Livingstone. There was one Arab report in November 1870, that he was at the town of Manakoso, with few followers, waiting

* In English units.

for supplies, and unable to move; but the last certain intelligence was that be three years old on the 30th of next May. The question now is, shall this great and noble-hearted man be left to his fate? In January 1870 the Treasury sanctioned a grant of 1,000*l.* to send stores by natives from Zanzibar through the political agent; but this method of affording relief failed, and neither letters from Livingstone nor proof that he ever received the stores have reached the coast. Mr. Stanley, an American traveller, has also attempted to penetrate into the interior, but he was stopped by disturbances at Unyamwe. It has thus become clear that, if Livingstone is to be relieved, a properly equipped expedition, ably commanded, must be despatched from this country to do the work. The Lords of the Treasury have declined to grant any pecuniary aid to the expedition which is destined to bring succour to Dr. Livingstone, who, it must always be remembered, is Her Majesty's Consul for the interior of Africa. No adverse decision from the Treasury will, however, be allowed to check the necessary preparations, nor to retard them for a single day. The known facts upon which the Council of the Society have had to base their decision are few, but they all pointed to one obvious course. According to the latest rumours, which were to some extent corroborated by the great traveller's expressed intention, Dr. Livingstone is in the Manyema country, to the westward of Lake Tanganyika, where he may be prostrated by sickness, and where, at all events, according to his last letters, he was urgently in want of supplies. As experience has proved that it would not be safe to entrust the charge of supplies to the Arab traders, the only alternative is to despatch a relief expedition led by Europeans, and the Council of the Society had determined on that course. The fortunate accident that an excellent opportunity offered itself of reaching Zanzibar in the first steamer that has ever made the direct voyage by the Suez Canal was a sufficient reason for the rapidity with which it was necessary to prepare and despatch the expedition. Nearly 200 persons had volunteered to take part in the expedition, and the choice of a leader had fallen upon Lieut. Llewellyn Dawson, R.N., a scientific seaman, who possessed most of the qualifications which were needed to fill so difficult and trying a post, and in whose ability and judgment the Council had perfect confidence. It was intended that he should be accompanied by a second in command, and the Foreign Office had applied to the Admiralty that any naval officer who served on this expedition should be rated on one of Her Majesty's ships, so as to be allowed time and full pay. Mr. W. Oswell Livingstone, Livingstone's son, who was born twenty years ago in the neighbourhood of Lake Ngami, would also accompany the expedition. It was hoped that Mr. New, a gentleman connected with the Mombasa Mission, would act as interpreter, and the party would in all consist of an escort of about fifty picked men, besides porters. It would leave England early in February in the *Alyda* steamer, chartered by Messrs. J. Wiseman and Co., who had generously undertaken to convey all stores free of charge, and, if possible, to secure reduced charges for passages for the members of the expedition." A discussion ensued on the reading of this statement, in which Mr. J. R. Andrews, Dr. Purcell, Mr. Lee, Mr. J. Ball, Admiral Collinson, Mr. Thorpe, the Rev. Horace Waller, and others joined. The letter from the Treasury declining to aid was called for and read, and comments made on the possible meaning of the chief sentence in the letter—"A new expedition is not the only means left through which Dr. Livingstone's safety may with reason be hoped for." The following communications were read:—1. "Letter to Dr. Kirk on an Ascent of Kilimanjaro." By the Rev. Charles New, of Mombasa. This letter describes the recent visit of the author to Chagga and his ascent of Mount Kilimanjaro to the snow-line. Mr. New had made a collection of plants growing in the upper zones of vegetation on the mountain which he had forwarded to Dr. Hooker at Kew. He described the varied zones, from the tropical country at the base of the mountain up to the magnificent snow-coloured dome which forms the summit. The lower slopes were covered with dense forests of gigantic trees clothed with mosses, the upper of heaths and green pastures. 2. "Ascent of the Padass River and Visit to the *Muruts* Country in Northern Borneo." By Lieut. C. de Crespiigny, R.N. This journey was undertaken in the search of orang-utangs or *Afars*, which abound in that part of Borneo. The Padass rises on the slopes of the lofty mountain Kiti-balu, and flows through a plain furrowed by the courses of many other rivers. Much information was given concerning the *Palaus* and *Muruts*, and other little-known tribes, and cases of the employment of orang-utangs as domestic servants, employed to collect fire-wood, &c., were given.

Entomological Society, January 22.—Mr. A. R. Wallace, president, in the chair.—The Rev. T. A. Marshall, and Messrs. H. W. Bates, A. Müller, and F. Smith, were elected into the council, to replace members retiring therefrom. Prof. Westwood was elected president; Mr. S. Stevens treasurer; Messrs. McLachlan and Grut, secretaries; and Mr. Janson, librarian. The retiring president read an address, and the meeting ended with the usual votes of thanks to the officers.

Victoria Institute, January 22.—Mr. Charles Brooke, F.R.S., in the chair.—Dr. W. M. Ord, "On the influence of colloid matters upon crystalline forms," illustrated by numerous diagrams and specimens. Having briefly defined the use of the terms, he proceeded to show that when crystalline substance was deposited in a colloid, such as gum or albumen, it assumed not a crystalline, but a globular form. Diagrams showing the various changes that took place illustrated this part of the lecture. The action of salt water on the carbonate of soda in the case of the shell of the lobster, and the changes in the organisms were explained; the formation of bone in hawk-man tortoise and the codfish were alluded to, and Dr. Ord concluded by drawing attention to the importance of the investigation of the chemistry of colloids.

GLASGOW

Geological Society, January 11.—Mr. John Young, vice-president, in the chair. Mr. James Thomson, F.G.S., read a paper on *Paleocoryne scoticum* and *P. radiatum* from the carboniferous shales of the West of Scotland. He stated that at the first excursion of the society to Corrieburn, in 1858, he had observed in some portions of shale a small, delicate, stellate body which he could not refer to any genus or species he had seen described. Since then, at various Saturday afternoon excursions of the society, he had discovered other forms of a similar kind. He had consulted the collections of the Geological Society, the Government Museum of Practical Geology, and the British Museum in London, without finding any similar organisms; and lacking the necessary facilities for prosecuting the work himself, he had at length placed them in the hands of Prof. Duncan, in order that they might be identified and named. On investigation Prof. Duncan found them to be new and undescribed forms which could only be referred to the *Hydrozoa*. The calcareous investments of these *Paleocorynida* made their recognition as true *Hydrozoa* a matter of some difficulty; but this had been overcome by the examination of the anomalous genus *Bimeria* (Wright), which, as pointed out by Prof. Duncan, shows a very decided resemblance to the fossil under consideration, the semi-solid investment being continued over the greater part of the tentacles and upper part of the body. These minute but interesting forms are found both in our highest and lowest beds of limestone—at Roughwood, Broadstone, Auchinskeigh, and Gare—and their discovery may be said to add another link to the chain that unites the present with the remote past.—Mr. Thomson also gave notes on a new species of *Palachinus*, from the limestone shale of Auchinskeigh. It was most nearly allied to Dr. Scouler's species *spharicus*, but differed in the form and ornamentation of both the ambulacral and interambulacral plates. He proposed to name it provisionally *Palachinus scoticus*. Mr. Thomson exhibited the fossils and some beautiful microscopic sections in illustration of his paper.

PARIS

Academy of Sciences, January 22.—A paper by M. J. Boussinesq on the geometrical laws of the distribution of pressures in a homogeneous and ductile solid, subjected to plane deformations, was communicated by M. de Saint-Venant.—M. Faye read a note on Encke's comet and the phenomena which it presented at its last appearance.—A sixth letter from Father Secchi on the solar protuberances was read, containing a tabulated summary, with explanations of all the observations made upon the protuberances during the year 1871.—M. Trémaux forwarded a note on phenomena indicating the condition of the sidereal medium.—M. Delaunay communicated a note by MM. Prosper and Paul Henry, on the construction of very detailed celestial maps, and exhibited a map prepared by them on the principle indicated.—A note on the Meteorological Annual of the Paris Observatory for 1872, by M. E. Renou, was read; the author criticises some of the numerical results given in that volume.—M. E. Dubois presented a note on a marine gyroscope.—M. H. de Jacobi communicated his researches on the induction currents produced in the coils of an electro-magnet between the poles of which a metallic disc is set in motion; this paper contains

THURSDAY, FEBRUARY 8, 1872

THE FOUNDATION OF ZOOLOGICAL STATIONS

WHOEVER contemplates a little closely the state of Science at the present time, must be struck with the fact that, whilst in almost every other branch of public and private life co-operation has been established, and has worked out great results, its influence on the life of Science is but small and insignificant.

This may sound strange to all those who know the number of Scientific Societies, Academies, and Unions to be found in England, Germany, America, Italy, France, in short, everywhere where Science is cultivated at all. But if one looks into the life of these societies, there is not much co-operation to be found in them. They publish periodicals; but there are publishers who do quite as well as societies, and sometimes even better. They meet and talk science; but this does not add much to the real progress of science. Sometimes they found museums or cabinets, and this is a better service; they establish a library for the use of their members, and this is perhaps the best they do altogether. A man may be fellow of twenty different societies, but that will not affect much the progress of the scientific work he does; if he is member of certain academies his reputation may be raised in the eyes of the outside public, but no essential help is afforded by that either to him or to his work, except in the case where such academy has some influence on the Government, as, for instance, the Royal Society. The Menagerie in the Regent's Park, established by the Zoological Society, is one of the solitary instances in which, the initiative being taken by a scientific body, an institution has been evolved, drawing immense revenue from the public pocket, which is for the most part spent upon scientific objects. It is the application of this method of securing support which will be strongly advocated in the present paper, as a practicable path for the future progress of biological research.

There is also another great society in Britain which does, perhaps, better work for science than any other. This society is the British Association for the Advancement of Science. Not only does its great and well-deserved reputation make it powerful and influential, but also the large sum of money it distributes annually for the direct progress of science. This influence is due principally to the fact that the best men in British Science participate with great eagerness in the meetings of the Association and lend to it all their personal authority and reputation. The considerable sum of money to be distributed is due to the great number of scientific and lay people that take part in its meetings.

The combination of these two elements ought to be imitated in every special branch of science. The times are past when great scientific men did not condescend to speak to a general public, and happily nobody believes any longer that science must be lowered and lost, because the general public looks at and hears a little of its inner life. Great scientific men have an immense influence upon the public, and that is an immense benefit to the public; on the other hand, the general public takes interest in, and

pays money for the progress of science, and that is a great benefit for science.

The meetings of the British Association therefore are an essential step in the right direction for lending science the great help of co-operation. But a great deal more of it is needed if that element is to supersede by-and-by the old lines and ways of mere individual and disorganised action. Especially is co-operation wanted in the single sciences. Every one knows how great is the progress in meteorology and astronomy brought about by the possession of special laboratories and observatories. Even if all the universities were extinct at once, these sciences would go on perfectly well by the help of the observatories. Chemistry is aided by innumerable laboratories, erected for practical purposes. Mechanics governs the world and finds itself at home everywhere, involving by its special character many elements of co-operation.

Other sciences do not enjoy these privileges, though they want them perhaps even more than some of those that are in possession of them. Amongst the number of these sciences, perhaps the most neglected in the way of co-operation is Biology, that science which occupies at present such an eminent place in the public interest, and yet the most neglected, in so far as no other science feels at present the necessity of co-operation and organisation so much as biology. The reason is a very obvious one. Biology has undergone a complete revolution by Mr. Darwin's great work. This revolution has augmented the number of special problems in such enormous proportions that biology is now completely at a loss to solve all these problems by the aid of the means placed hitherto at its disposal, and looks pretty much like a boy who has suddenly grown in one year out of all his clothes, presenting the ridiculous aspect of a man in a child's dress. The thing which a father would do for his boy would be to go and buy another dress. This obviously was also the idea of Prof. Carl Vogt, who long since began an agitation for the establishment of a zoological laboratory at the sea-coast, of which agitation he wrote me in a letter the following account:—

"During the years 1844—1847 the plan for the establishment of an expedition was worked out at Paris by Milne-Edwards, and I participated in it. The object was the investigation of a coral-land, and the establishment of a station upon it for at least several years. The ship and the station should be furnished with all possible things, especially for dredging-work. The scheme fell to pieces owing to a question of etiquette. The commander of a man-of-war of the Royal Navy would not submit to the direction of a naturalist.

"As you know, I lived from 1850 to 1852 at Nice. The instruments for observation, which I bought by the money earned by literary work, consisted of a microscope, a surface net, and some large sugar-bottles. I tried at the time by the help of two deputies, my friends Valerio and Dunico, to bring about the foundation of a zoological station at Villafranca, asking only for some rooms in the empty buildings of the Darsena, and the establishment of some tanks in them. Nevertheless I had not the least success.

"In the year 1863 my friend Matteucci became Minister of Public Instruction in the kingdom of Italy. With him, as a physicist who especially dealt with physiological subjects, and who, understanding the necessities and wants

of physical science, intended to make important reforms, I easily arrived at a mutual understanding. It was his idea to elevate the studies in Italy by introducing foreign, especially German, scientific men into the chairs at the universities, who should teach the new generation of Italian students. I worked out for him a project for the erection of a zoological station at Naples, the most suitable place in Italy. The Casino Reale at Chiatamone was to be transformed and fitted up for such a purpose, and a little steam yacht for dredging was to be placed at the disposal of the station. The latter was in the meantime intended for a sort of school, connected with the whole system of public instruction, to form teachers of natural history for the whole kingdom. The plan was completely worked out and adopted by Matteucci and several others among the first scientific men of Italy. They applauded it heartily; Filippo de Filippi especially did everything he could to bring it into play, and talked about it, as he told me, to King Victor Emmanuel during a hunting-party. Matteucci afterwards left the ministry—Filippi and he are dead—the fate of the project is easily to be understood.

"Thus I had got round the Mediterranean. In January 1871 I was at Trieste delivering public lectures. On January 8 I published in the *New Free Press* two letters on 'Some Necessities and Wants of Scientific Investigation,' the subject of which presented itself to my mind when viewing some of the Austrian arrangements for public instruction. I may be allowed to say that my article met with universal approval; and some Triestian friends, amongst whom I may mention especially Field-Marshal Lieutenant v. Möring, at the time Governor of the Coast District, talked with me on it, and agreed that Trieste would be a very good place for the execution of my project. Möring himself directed my attention to some small buildings at Miramare, lying outside the park; we visited them together and talked about the necessary arrangements to be made. I worked out a fresh project, made rather special calculations on the money necessary for executing it, and sent all this to the Austrian Minister of Public Instruction, Herr v. Stremayr, with whom I spoke on the subject afterwards, when I passed through Vienna. As you know, I addressed at the same time Gegenbaur, Haeckel, and you, to approve my views and assist me. You sent me besides a letter from Darwin, who applauded much your own plan for erecting a station, and had even offered a subscription for it. I added all these letters to my memorial, which unfortunately had the same fate as the Italian: Stremayr left the ministry before he could do the least thing for the realisation of a plan which he thought exceedingly valuable."

Though Prof. Vogt did not succeed in carrying out his plan, there can be no doubt that his idea is the very one wanted for the present state of biology. A great number of other zoologists entertained it, but nobody knew how to execute it.

In the winter of 1868-69 I found myself at Messina, occupied with the investigation of the embryology of Crustacea. Together with my friend Miclucho Maclay I often spoke of the necessity of establishing a zoological station on the coast of the Mediterranean, and we agreed to leave a considerable quantity of instruments, amongst which was a small aquarium furnishing a constant stream of water, to our successors in Messina. An Austrian squadron, just sailing round the globe with a considerable number of natural-

ists, amongst whom were Herr v. Scherger and others, stopped several days in the harbour of Messina, and caused me many thoughts about the great advantage such and other expeditions would derive from a net of scientific stations stretched over the whole globe.

But how to get anything like such stations built and kept up for years? I did not know at that time that Prof. Vogt had already tried to get assistance from several great governments, and had failed to succeed. But I did not even try to do anything like this, knowing beforehand that it would be useless. Zoology is at present in a rising condition, it has still to conquer the place it ought to occupy in the attention of the public by making itself indispensable to intellectual progress. As it is, governments will not easily be induced to sacrifice much money for the progress of this science.

I took another line. After some unsuccessful attempts to get money by collecting small sums, I combined the idea of founding a scientific station with the plan of building a great public aquarium at Naples. My calculation was, that by the entrance-fee of that aquarium the sums necessary for keeping up the station could easily be obtained, and that perhaps more than that would come out of it. I saw at a certain distance even the possibility of erecting other stations with the surplus of the Naples income, and of giving in such a way quite a new development to biological science, just that development which biology wanted after the great event of the Darwinian theory.

As soon as I had got a hold at Naples, I began to spread my ideas in letters and conversations. I the pleasure of finding almost everybody in England and Germany quite ready to assist as much as possible. I brought the subject before the meeting of the British Association in Liverpool, and succeeded so far that a committee was appointed by Section D, composed of Prof. Rolleston, Dr. Sclater, and myself as secretary, under the name of "The Committee for the Foundation of Zoological Stations in Different Parts of the Globe."

This was during the war between Germany and France. While it lasted it was almost impossible to do anything in favour of the scheme I had got into my head, except thinking and meditating upon it as much as possible. But as soon as peace was made I proceeded again, as well with the negotiations at Naples as with agitation in other countries.

As secretary of the above-named committee, I gave a report to the meeting of the British Association at Edinburgh. I stated in that report that the establishment at Naples was now quite safe, so far as the permission of the Town Council was concerned; and that, in all probability, the station would be seen there in working order in January 1873. I added that I had got the assistance of my own Government, and I may add here that the Italian Government also assists me greatly. I proposed further in my report that the British Association might consider the opportunity given by the cessation of the annual grant to the Kew Observatory, of building a zoological station at one of the most favourable places on the British coast. My idea in proposing this was based on the same considerations which had made me go to Naples. I thought it very convenient and very practicable to build a small station, for example, at Torquay or Plymouth, and to combine in such a station, in the same way as at

Naples, a laboratory with a larger aquarium for the public. The income of the latter in a place like Torquay, where there are so many residents and visitors at all times of the year, would completely suffice to keep up the laboratory, and pay a modest sum to a naturalist, who would be charged with the management of the station. Being unable to attend personally the meeting at Edinburgh, I could not give all the reasons which induced me to make this proposition. All the more I shall avail myself of the present opportunity to do so.

The present state of zoology requires, as stated above, new means of investigation. Systematism and simple faunistic researches fall very far short of the problems now ripe for solution. Two great departments of biological science go much ahead of all others, and these two are embryology and the study of the life of animals in relation to all those conditions which regard the struggle for existence and the action of natural selection.

If we speak first of the latter chapter, it is clear that past times have done much more in promoting knowledge about it than the present generation. It is rather out of fashion to study the habits and conditions of life of an animal. Systematism, the making of genera and species, have so much exceeded their legitimate grounds, that they have almost completely suppressed that other branch of natural history. We owe it to Mr. Darwin that he completely upset this one-sidedness, in proving, by his admirable treatises on the Domestication of Animals and Plants, on Sexual Selection, on the Fertilisation of Orchidæ by the Interference of Insects, of what fundamental importance these studies of the habits and conditions of animal life can be. He added not only an enormous number of hitherto unknown facts to the storehouse of science, but he showed what immense importance these facts gained by deriving from them the great principle of natural selection—a principle as grand as any in modern science. Very few zoologists (in naming Mr. Wallace and Mr. Bates, I do justice to these eminent men as two of those who promoted these studies independently of Mr. Darwin) have followed Mr. Darwin's lines in these departments. Nevertheless this must happen: it constitutes one of the most urgent necessities of biological study in our time, and it must not only be done for our domestic animals, and those that live most closely around us, but wherever animals are to be found, and so above all in that enormous field of animal life which occurs in the sea.

Every one will agree with me that we know scarcely any of the secrets of the life of the sea bottom. We have short notices on the habits of some fishes; but this is altogether insignificant compared with the immense bulk of things unknown to us in the same department. And of echinoderms, cuttle fish, jelly fish, polyps, &c., &c., our knowledge simply amounts to nothing.

Here an aquarium, under scientific guidance and superintendence, can work immense good and progress. And such an aquarium will do double service; first, it will attract the public and yield money; and then it will serve immediately and directly the progress of science, by giving the only possibility of knowing something about the habits and the life of marine animals.

But a zoological station with an aquarium will serve equally as much for the progress of embryology. Whoever looks at the development of biological science must

see that, during the last ten years, embryology has made very important progress, not only in accumulating facts, but in rendering them serviceable to the progress of ideas and principles.

An offspring of the theory of descent is the maxim that the ontogenetical development is an abbreviated recapitulation of the phylogenetical development. This maxim, or law, if we choose to call it a law, gives enormous importance to embryology. By the help and application of it we may succeed in getting a deep insight into the history of animal life long before the geological record. The Cambrian and Silurian systems yield us already a fauna of so high perfection, and so complete a series of representatives of almost every great class of animals, that we could easily be led to believe in a waving up and down of animal creation, not in a constant progress, so comparatively small are the differences between the present fauna of the earth, and those which the geological record of all the strata makes known to us. Embryology, on the contrary, starts at the very beginning of organic life, tells us how out of simple organic matter cells became formed, how these cells took different functions, thus differentiating and organising the being that possessed them. Embryology further tells us how out of one form, one single form, whole classes came forth, and renders it possible for us to trace the lines of origin of every member of these classes, down to the common ancestor of all of them.

Systematists, looking out anxiously for the "natural system" of the animal kingdom, and turning to mere anatomical differences, may be compared to Sisyphus rolling his stone. They cannot succeed without taking to embryology. But embryological studies are among the most difficult in the whole range of biological science. Not only the interpretation of the facts, and the conclusions to be drawn from observation, require an immense amount of circumspection, caution, and critical ability; but even the simple statement of a fact, the mere act of observation, is often exceedingly difficult. How many monographs on the embryology of the chicken have been written since Caspar Friedrich Wolff published his immortal book against the doctrines of Haller. Pander, Baer, Remak, His, and many others, have treated the same subject, and still to-day there is uncertainty on the most fundamental questions. This is above all to be attributed to the mechanical difficulties of observation. And these difficulties do not exist only in the case of birds' eggs; they are the same for the eggs of almost all animals, especially for those of marine animals. These require a constant stream of salt water to keep them alive, a stream which is only to be had by the help of an aquarium. It is principally due to the absence of such aquariums that our knowledge of the development of fishes is still so rudimentary; for, though the works of Baer, Rathke, Vogt, Lereboullet, Kupffer, and others have taught us a good deal, nevertheless the essential parts of fish-embryology are still wanting. And this is the more to be regretted as it cannot be doubted that the eggs of fishes are, in many regards, preferable as objects for the investigation of general embryological facts to those of the birds. Considering only the fact that all other vertebrata have proceeded from fishes, most likely from shark-like animals, it will be of the greatest importance to acquire

convenient methods for investigating the embryology of these animals.

Besides, the enormous mass of other marine animals waits equally for the establishment of laboratories provided with aquariums, before the study of their embryology can safely, and with due prospect of success, be taken in hand. And that the common ancestors of all the higher animals have lived in the sea, and must have left the traces of their nature still in the embryos of marine animals, is more than likely. Every attempt, therefore, to get back to these ancestors, and to build up scientific genealogy, must lead to the investigation of the embryology of marine animals, must cause, in consequence, the desire of having laboratories near the coast, provided with tanks and continual streams of sea water, to overcome the mere mechanical difficulties of the study.

These are reasons of the most imperious nature to move all those who can do something, to combine their exertions for the foundation of zoological stations near the sea-coast.

When I therefore proposed, in the name of the Committee for the Foundation of Zoological Stations, the erection of such a station at Torquay, my principal object was to create a greater facility for English zoologists to execute scientific works of the above-mentioned nature. Without denying one moment the immense benefit zoology has always derived from English naturalists, one may justly lament that embryology has not found so many students in a country which has such great opportunities of following the study as, for example, has been the case in Germany. England abounds in splendid localities for the study of marine animals; the innumerable harbours, firths, and bays yield an immense material for the scientific observer. Students at the universities would have the easiest access to these localities, and would gain a great mass of information from them; but circumstances have directed almost the whole scientific spirit in another direction—almost all the biologists are occupied with the completion of the faunistic records of the English seas. The existence of a zoological station at Torquay must lead to a greater cultivation of the other branches of marine zoology by Englishmen, and must open also for foreign zoologists the opportunities yielded by the fauna of the south coast of England for carrying in studies in comparative anatomy and embryology.

It will be essential, not only for the progress of zoology in general, but also for the development of the whole scheme for the foundation of zoological stations, that those countries which contribute by their natural position most to the progress of marine zoology should be provided first with zoological stations. If zoological stations in other parts of the world outside Europe are to be founded, they will require above all zoologists to conduct them. Where are these at present to be found? Nowhere, I believe. If, therefore, the great object of my plan is to be attained, it will only be by gradually and consistently developing its base—the foundation of stations in Italy, Britain, France, Norway, and perhaps Spain or Portugal. With the help of these stations, zoologists may be educated who would be inclined to go to remoter places, such as, for instance, Capetown, Ceylon, Japan, or Australia, and conduct or work only for a couple or more years in the stations built in those countries. There can be no doubt

that the benefit for science would be enormous if there existed efficient working stations in these countries; but to make them efficient the principal means is to give them well-instructed naturalists at their head, and this is at present not possible.

Therefore I take the opportunity of repeating once more that it seems to be essential to proceed with the foundation of a zoological station at Torquay, and to head that station by a young, laborious zoologist, who is already experienced in histological and embryological work. It cannot but be that science, and especially British science, will derive considerable benefit from such a proceeding.

Naples, Jan. 2

ANTON DOHRN

THE NATURAL HISTORY OF EGYPT AND MALTA

Notes of a Naturalist in the Nile Valley and Malta. By Andrew Leith Adams, M.B. (Edinburgh: Edmonston and Douglas, 1871.)

FEW men have better opportunities for furnishing valuable contributions to the Natural History of foreign parts than surgeons attached to the Army and Navy; an education in at least the rudiments of natural science, combined with abundant leisure, presenting means which are not at the disposal of all travellers. As a rule, we fear that this class of men have done but little for Science compared with what might have been expected of them. There are, however, some honourable exceptions, among them our present author, whose "*Wanderings of a Naturalist in India*" has been already given to the public, and who now publishes the results of the labours of his leisure hours and vacation rambles in the investigation of the archaeology and natural history of the Lower Nile and Malta.

The most interesting portion of Dr. Adams's researches in Egypt and Nubia relates to the evidence as to the period when the northern portion of the African Continent became elevated above the sea. On this point he says:—

"The discovery of the common cockle and other marine shells far inland, and over vast tracts of Algeria and the desert of Sahara, even up to height of more than 900 ft. above the present level of the Mediterranean, and at a depth of 300 ft. below it, fully establishes the fact that a large portion of North Africa was, at no very distant period, covered by the ocean; moreover, that the highlands of Algeria, Tunis, Morocco, and Barbary, were at this period separated from Africa by sea, and that the submergence occurred during the modern or post-tertiary period. Further researches have also proved that the same description of phenomena are to be observed along the borders of the Red Sea. A question therefore suggested itself to me in 1863, whether or not Egypt and Nubia had participated in the same continental movements. Accordingly, no opportunities were omitted during our short sojourn in Lower Egypt in searching for similar evidences of upheaval and depression, but, owing to the flatness of the country, drifting of the desert sands, and great expanse of cultivation on the river's banks, and our rapid movements, I was unable to discover any traces. It was not until we approached the frontier of Nubia, and passed the first cataract, that favourable opportunities were presented. The Nile, now contracted by the porphyritic and sandstone rocks, flows between steep banks, and creating accumulations of alluvium and bendings and openings in

its course, the desert may be said to come down to its margin.

"Wherever these Nile deposits exist, there may be seen clusters of date and doom palms, and fields, whilst further back stand the mud-built villages of the natives; and still more inland are observed plateaus and terraces at variable levels, covered with finely rounded angular stones and drifted sand. These terrace cliffs continue, with broken intervals, from below the first cataract up to the extreme point attained by us at the top of the second cataract. The observer may have some difficulty at first in tracing these river terraces, but, after a little experience, there will be no trouble in making them out. Let him proceed from the river (1) across the alluvial plain (3), on which stands Der, the capital of Nubia, to the ruined temple (4) of Rameses the Great, on the verge of the cultivated tract, then mount the plateau immediately above (5), and wander inland until he gains a height of 130 ft. above the highest mark of the inundation (2), and commence digging among the stones, when he will come to a reddish-brown soil, highly impregnated with natron, which the natives collect for top-dressing on their fields below. There he will find abundance of Nile shells distributed throughout the soil from the margin of the cliff above the temple inland for upwards of a mile, and until the drifted sand of the desert makes it difficult or impossible to trace them further; indeed, the same appearances are observable along the right bank of the river throughout the

distance just indicated. These fossil fluviatile shells belong to species nearly all of which have been proved to exist in the Nile at the present day, and comprise the following species, determined from specimens sent to the Geological Society of London, and examined by the late eminent conchologist Mr. S. P. Woodward:—*Unio lithophagus* (?) *Bulimus pullus*, *Paludina bulimoides*, *Aethria semilunata*, *Cyrena fluminalis* and variety *trigona*, *Iridina nilotica*."

From these data Dr. Adams concludes that Egypt and Nubia participated in like movements with other portions of the Continent to the east and west; but whether or not, in common with them, they were entirely submerged under the sea at the same epoch, is not so clear, as no marine shells have yet turned up in either Egypt or Nubia.

At Malta, the author's researches were chiefly devoted to an investigation of the fossil mammalian remains in which this group of islands is so rich, for which purpose the British Association, at the suggestion of Dr. Falconer, Mr. Busk, and Captain Spratt, voted 60*l.* in 1863 in aid of his explorations. These Maltese mammalian remains are of unusual interest, comprising the *Hippopotamus Pentlandi*, an animal about as large as the existing Nile species; the *Elephas melitensis* of Falconer, or Pigmy

Maltese Elephant, not more than $4\frac{1}{2}$ ft. in height; the still smaller *Elephas Falconeri* of Busk, the average height of which at the withers could not have exceeded $2\frac{1}{2}$ to 3 ft.; a new large species, named by Dr. Adams, from the place of its discovery, *Elephas Mnaidra*, the Gigantic Fossil Dormouse, *Myoxus melitensis*, described by Dr. Falconer to be "as big in comparison to the living dormouse as the bandicoot rat to a mouse," and the Hollow-jawed Dormouse, *Myoxus Carlei*, another new species detected by the author. Conspicuous among other vertebrate remains are those of the Gigantic Swan, *Cygnus Falconeri*, another large swan, several other species of land and water birds, at least two species of fresh-water turtles, and a lizard.

With regard to the recent Molluscan fauna, a small land-snail belonging to the genus *Helix* has been found near St. Paul's Bay, and on the bare limestone cliffs of the west highlands of Gozo two recent shells of the genus *Clausilia*, not apparently found in the adjoining continent or Sicily; and at present these represent the only living animals that can be said to be peculiar to the Maltese Islands. Lists of the fishes and birds of Malta are given at the end, the majority of the latter being birds of passage, with respect to the habits of which some interesting particulars are given.

We have no information with regard to the vegetable productions of the island, and this is to be regretted, as observations made during so long a residence would doubtless have elicited some new and interesting facts. The author, however, has probably acted wisely in not trusting to second-hand information which his own botanical knowledge would not have enabled him to

verify. We find the well-known *Cynomorium* of Gozo, the *Fungus melitensis* of the Knights of St. John, a flowering plant, spoken of as a lichen.

The volume is illustrated with some well-executed woodcuts and lithographic plates, and we recommend it to all interested in the subject.

OUR BOOK SHELF

A Synonymic Catalogue of Diurnal Lepidoptera. By W. F. Kirby. (London: Van Voorst, 1871.)

THE great work on the "Genera of Diurnal Lepidoptera," by Doubleday and Hewitson, completed after the lamented death of the former by the assistance of Prof. Westwood, included under each genus a synonymic list of all the described species which the authors were able to determine. But more than twenty years have elapsed since the completion of this most valuable work, which still remains without a competitor either in this country or on the Continent, and thus our means of reference upon systematic matters connected with the beautiful and interesting group of butterflies generally, have remained at what must be regarded nowadays as a somewhat antiquated standpoint, whilst the business of describing has been carried on with the most astonishing energy. In Britain Doubleday's collaborator Hewitson, and his successor Butler, have described an almost inconceivable multitude of new species, and a considerable number have also been added to the list by Bates and Wallace; whilst on the Continent the Brothers Felder and Dr. Herrich-Schäffer have been equally active. New views have also been put forward as to the natural sequence and limitation of the groups (families and subfamilies) into which the great Rhopalocerous tribe is divided, and the

whole face of this department of entomological science has undergone a wonderful change in the last twenty years.

Under these circumstances many an entomologist has no doubt often wished that a new "Genera of Diurnal Lepidoptera" would make its appearance; but such works are not to be lightly undertaken, and it may be long before we can hope to see a good, general, systematic treatise upon this group of insects. In the meanwhile we welcome Mr. Kirby's catalogue as a most important aid to the study of the Diurnal Lepidoptera. It is a complete catalogue of the described species of the group, amounting, as an estimate, to about 9,600 in number, and gives the synonyms both of the genera and species in a clear and easily-intelligible form. With the assistance thus offered to him by Mr. Kirby, the entomologist may easily ascertain what has been done by former writers in this department of his science, and it will be his own fault if he does not keep himself *au courant* with its future progress.

Criticism upon a work of this nature would be out of place here, and we can only cordially recommend the results of Mr. Kirby's most conscientious labours to the attention of all entomologists.

A Class-book of Inorganic Chemistry, with Tables of Chemical Analysis, and Directions for their Use. By D. Morris. B.A. (London: G. Philip and Son, pp. 157.)

THIS work has been compiled for the use of students preparing for the Oxford and Cambridge Middle Class Examinations, and the Matriculation Examination of the University of London; it lays claim to no originality of treatment, and professes to be simply a collection of "enlarged notes," "originally culled from the best modern books." Under these circumstances we are somewhat surprised that the author should have ventured to publish it; we are quite unable to detect any special merit in the book, and it is disfigured by many passages which show great want of exactness. Thus, we find "nitric acid, or nitric anhydride, N_2O_5 ;" "sulphate of potassium or dipotassic sulphate;" the formula of phosphate of calcium is written Ca_2PO_4 , of chloride of lime CaOCl_2O . We are told that "ammonium and sodium are distinguished by the smell of ammonia on the addition of caustic potash." "Pure water has no action upon the metal (lead), but water charged with air corrodes it, and the oxide of lead thus formed dissolves in the water." Among the redeeming qualities of the book may be mentioned the questions which are selected from various University examination papers, and the examples given worked out in the text; but with errors of the nature of those given above it is impossible to recommend the book to the student, or to regard it as a reliable source of information.

The Elements of Plane Geometry for the Use of Schools and Colleges. By Richard P. Wright, Teacher of Mathematics in University College School, London, formerly of Queenwood College, Hampshire. With a Preface by T. Archer Hirst, F.R.S., &c., late Professor of Mathematics in University College, London. Second Edition. (Longmans, 1871.)

THIS work would have been more correctly described as being "by Eugène Rouché and Ch. de Comberousse, translated and edited by Richard P. Wright," &c. But although Mr. Wright can lay small claim to originality, he has shown judgment in the selection of an eminently logical and masterly treatise on geometry, and he has rendered it into clear and forcible English. The arrangement is excellent, and many of the conclusions for which Euclid found it necessary to reason geometrically on each particular case are treated generally by purely logical considerations. Many of the demonstrations, notably that of the *pons asinorum*, are far more simple and con-

vincing than those in Euclid. The difficulty of the twelfth axiom is met by the easy axiom that *through a point without a line only one parallel can be drawn to that line*. In some points there seems to be an unnecessary alteration of the language of Euclid, as in the definition of a figure, "Surfaces and Lines or combinations of them." This definition seems to have been introduced to enable the authors to describe a *locus* as a figure; but it having been pointed out that a *locus* is not a figure, Mr. Wright has described it as a *line*, but has not restored the word figure to its ordinary acceptance. At the same time it is not quite correct to define a *locus* as a *line*, excluding such loci as a pair of parallel lines, the circumference of a circle with its centre, &c. Again, the word *circumference* is substituted for the word *circle* whenever the circumference only is intended. It is true that the word *circle* in Euclid is used in two different senses, but this leads to no ambiguity of ideas; while the use of the word *circumference* for the circumference of a circle only excludes its application to an ellipse or other closed curve. The word *angle* is not defined when first introduced, but we are told afterwards that it "may be regarded as the quantity of turning of a definite character around the vertex, which a movable line must receive in passing from the direction of one side to that of the other." We fail to see the force of the words "of a definite character," and would suggest the following definition: "When a straight line moves about a fixed point in itself so as to occupy a new position, the quantity of turning it has undergone is called the angle between the two positions." The exercises are in. enious and instructive, but those of the earlier chapters are much too difficult for mere beginners. The treatment of proportion is good, and the work as a whole is an admirable introduction to the higher mathematics, and a great help to independent investigation. We especially recommend it to students who have found themselves discouraged by the cumbrous form and initial difficulties of Euclid. The second edition contains the alterations suggested by a late eminent mathematician in the *Athenæum* on the appearance of the first edition, with the addition of the substance of the second book of Euclid, and in a few cases the demonstrations of Euclid have been restored. H. A. N.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

The Aurora Borealis of Feb. 4th

AFTER a rather long absence of auroral displays, a brilliant and many coloured example was seen here last night, February 4, not quite so vivid as that of October 1870, but coming next to it so far as my own experience goes.

At about 8 P.M., when the maximum development was reached, all the heavens were more or less covered with pink ascending streamers, except towards the north, which was characteristically dark and grey, first by means of a long low arch of blackness transparent to large stars, and then by the streamers which shot up from that and along its whole length, for they were green or grey only for several degrees of their height, and only became pink as they neared the zenith, the region where the more precise phenomena occurred, as thus:—

1. The focus of the vertical streamers coming up from all azimuths was very constant among the stars, but was not in the zenith itself, being nearly 18° south and 5° east thereof.

2. The red streamers varied from orange to rose-pink, red-rose, and diamond-rose, or from strontium α , through calcium α , lithium α , and on to and beyond potassium α , that is, they did so to the naked eye, but the spectroscope knew no variety of reds amongst them; and I, having a very good referring spectrum in the lower part of the field of view, giving potassium α , lithium α , sodium α , citron acetylene and green acetylene, be-

sides the blue and violet, saw Angström's green aurora line perceptually over citron acetylene at W.L. 5579, and the red aurora line between sodium α and lithium α , but nearer to the latter, say at W.L. 6350.

3. Now, W.L. 6350 in the solar spectrum is a pretty bright scarlet red, so that orange could easily be made of it by the green aurora mixing therewith, and the spectroscope separates each of the two kinds of light with perfect ease. But how came potassium red or W.L. 7700, *i.e.*, the blood red, lurid red, and tragedy red of painters to appear so markedly to the naked eye, and yet not be seen at all in the spectroscope, either as a new ingredient or an altered place of the red line? It would apparently be by the mixing up of rays and streamers of the blackness out of that long, low dark arch on the northern horizon. But when a spectroscope fails (as fail it must) to show a characteristic line for a region of blackness, what other instrument can we take to prove the case?

Excessively faint greenish and bluish lines appeared at wave lengths 5300, 5100 and 4900 nearly; but the main light in the spectroscope was to the extent of 8-tenths of the whole, that of the green line 5579, and of 17-tenths the red line 6350; while to the naked eye the splendour of the display and its variety consisted in triple mixtures of 5579, 6350, and the unknown dark medium. Could something be ascertained about that, if those who have good telescopic star spectroscopes were to observe a star when shining through one of these inky black arches?

At 9.30 P.M. when all the aurora had faded or passed away towards the south, where a few straggling pink patches still appeared, the northern horizon and its sky being now free from the black arch, as well as the green streamers, perfectly astonished me by the clear pellucid blue of a true starlight night sky in a bright climate and clear atmosphere. Evidently the dark arch and streamers are as much a part of the aurora as the green and red lights, but how to investigate them—that is the question.

C. PIAZZI SMYTH

15, Royal Terrace, Edinburgh, Feb. 5

LAST evening an aurora of rather unusual brilliancy was seen here. I happened to be out with a friend in the country about sunset, when the sky was completely overcast and fine rain was falling. We noticed that darkness did not come on so quick as usual, and at 7 o'clock it was so light as to lead my friend to believe that the moon was shining above the clouds. Later in the evening slight breaks began to appear in the clouds, through which the first magnitude stars were just visible, and through these openings an intense red illumination appeared. The spectroscope gave from every part of the heavens a very bright line in the green, and another fainter one nearer the blue, together with a diffused light over the green and blue parts of the spectrum. The brightest part of the aurora was towards the S.W. From the large amount of light, although it was raining at the time, it must have been one of the brightest auroras that have been witnessed for years.

G. M. SEABROKE

Rugby, Feb. 5

COMING up the Channel on Sunday night last in the P. and O. screw-steamer *Delta*, about 9.40 P.M., I saw a very fine aurora. The sky was cloudy, which somewhat dimmed its brightness, but it was rather brilliant towards the N.

Having a Hoffman's direct vision spectroscope with me, I turned it towards the brightest red portion which lay towards the N.E., and with a moderate slit got a very sharp and distinct line in the green at or near the position of F in the solar spectrum. No other lines were visible. But on removing the telescope, and observing the spectrum with the naked eye, a fine crimson line revealed itself near C; the colour of it was exactly that of hydrogen α , as seen in a vacuum tube.

I also thought that there were faint traces of structure visible in the blue and violet, but of this I cannot be sure.

There had been traces of auroral phenomena visible early in the same evening. The green line was so distinct that unpractised observers saw it easily. The red line, however, was much fainter, and appeared to flicker.

I much regret that I had no means of recording the position of the lines.

R. J. FRISWELL

ABOUT six o'clock on Sunday evening the ruddy appearance of the upper clouds gave warning of an aurora in prospect, but I was not prepared for the magnificent sight which appeared on

looking out an hour later. The higher part of the sky seemed covered with bright rose-coloured clouds, which, from the dark masses of clouds passing underneath, seemed continually to be shifting in position. Intervals of deep green appeared amongst the red, and these, when looked at with a spectroscope, gave a stronger light than their surroundings. Objects near were illuminated as if the moon had risen behind the clouds. I had a miniature spectroscope of Browning's, with which I examined the brightest parts, and obtained four lines—one very bright green, two very faint nebulous green bands, and one red line. Having a spirit lamp handy, in which were remnants of sodium, lithium, and sulphate of copper, I was able roughly to estimate the positions of the lines. The red was about a third from *D* towards the lithium line; the very bright green about a third from *D* to the copper line near *b*, the other faint green bands were more refrangible, and I should think their places were between *b* and *F*, and near *F*, but I could not get their positions so well as the other two; certainly the most refrangible was not so far as the violet-potassium line which I could see in the field.

The light green was present everywhere, the red only showed occasionally with very varying intensity, and the most refrangible green line was also continually varying, but it was brighter than the second green line.

The light around attained its maximum about a quarter to eight, and then very slowly diminished to about midnight, when it had nearly disappeared. A light drizzling rain was falling the whole time.

J. P. MACLEAR

Shanklin, Feb. 5

THERE has been a magnificent red aurora here this evening. I saw it first before twilight had quite disappeared, and at first thought it was the crimson of sunset unusually late. It was at its finest between six and seven; at that time there were columns of light shooting up from the horizon almost to the zenith, and occupying almost half the horizon from the E. of N. round by E. The crimson colour was variegated with bluish white in a way that I have not seen before. The barometer was at about 29.45 inches, with a strong breeze from the south.

JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, Feb. 4

THERE was a fine display of aurora here yesterday evening. I first observed it about 5.30, just in the twilight, but it was then confused with the rays of the setting sun; as the darkness deepened the aurora came out alone, and was then extremely beautiful. It extended from the extreme N.E. to the extreme N.W., but from the reflection of the numerous clouds, appeared to have a much larger area. It was of a bright crimson colour, with the rays golden or orange, of which, however, only a very few were visible.

As the evening came on, about 8 o'clock, the clouds gradually became thicker, and at last almost entirely covered the sky; the only effect then apparent was a deep red glow, which continued with unequal intensity until 11.45, and with all probability much later. At 9.35 there was a break in the clouds towards the E., when the aurora shone forth in all its splendour. The aurora was most certainly visible in daylight, just appearing as the twilight came on.

I have no doubt if the atmosphere had been clearer, we should have had a most magnificent display; as it was, the effect was really beautiful.

J. S. H.

Gloucester, Feb. 5

THERE has been a magnificent and extensive auroral display this evening, of which I beg to send you the following account.

After a very heavy fall of rain, which lasted in this part of the country from 1 o'clock P.M. until 5.30 o'clock, there were collected in the northern horizon numerous *cirro-stratus* clouds, which gradually at first, and afterwards rapidly, moved towards the E., with the strata to the S. As these were passing away, I saw, about midway between these clouds and the zenith a bright patch of pale red light, which became well defined by 6 o'clock. A few minutes after this appeared I saw in the N.W. another patch of red light, and by 6.15 there stretched from N., N.W., and N.E. three very broad streamers converging in the zenith, and forming a splendid crimson canopy, the streamers being quite separated, until meeting, by dark spaces. These slowly disappeared, and of a sudden there appeared a bluish-white streamer stretching N.E. to and passing the zenith by about 10°.

At this time I could see that the Pleiades were partly covered, although not hidden, by a part of this streamer. At 6.35 it faded away. At 6.40 light clouds began to rise in the W. and S.W., and as I recognised this phenomenon as auroral, having seen similar clouds on other occasions of auroral displays, I carefully watched them, and saw at 6.50, in the S.W., a crimson-coloured patch, undefined in shape, originating from the light clouds. At 6.55 there shot up from the S. beautiful red, crimson, and blue streamers, which converged in the zenith. At 6.58 other bands of crimson and blue arose due S., and joined the others in the zenith. At 7.0 I was quite astonished to see the aurora appear in the S.S.E., by which time the previous brilliant display in the S. had dimmed, and the whole of them formed a southern canopy. During this southern display, the northern parts were quite dark, with heavy looking clouds; but at 7.5 the clouds slightly broke up, and I saw a faint redness in the N.E., about 45° above the horizon. By this time the southern streamers and patches began to spread and assume a mottled appearance, which reached by 7.10 the N.W. At 7.15 the N.W. and E. were quite dark and cloudy, and there remained only slight traces of the aurora in the S.W. high up in the heavens, and by 8.55 it had entirely disappeared.

JOHN JEREMIAH

Park, Tottenham, Feb. 4

DOUBTLESS many of your readers witnessed the magnificent aurora which occurred on Sunday, February 4. If any one else has noted the position of the radiant point, as seen from this station, the following observations, made somewhat roughly, from this place (lat. 53° 17' 8" N., long. 6° 10' 22" W., nearly) may be of use in determining approximately the height of that point above the earth.

At 7.15 (Greenwich time) its zenith distance was 23°; its bearing in azimuth 4° E. of S. At 7.30 its zenith distance was the same; its azimuth 15° E. of S. At 9.10 its zenith distance was 13°; its azimuth 1° W. of S.

M. H. CLOSE

Newton Park, Blackrock, Dublin, Feb. 5

LAST evening (Sunday, Feb. 4) there was a brilliant display of aurora visible in North Devon with some unusual features. At 6 o'clock the sky was clear, except a cloud of deep rose aurora over Orion, and another detached portion toward the west. This soon developed into a cloudy arch of the same colour stretching from east to west; then, a little south of the zenith between the Pleiades and Aldebaran, this arch culminated to an obtuse point of white cloud, something like a broad gothic arch. The northern half of the heavens was quite clear, but a series of radiations towards the south, and spreading east and west, issued from this point. For some time it seemed doubtful whether it was aurora, or a peculiar appearance of the clouds caused by high air currents, and a refraction of light from the sun's rays in the higher regions of the atmosphere. At one time there was some appearance of spiral radiations, or drift of cloud from this point near the zenith, with a distinct but irregular gap of clear sky, somewhat similar to the Coalhole in the galaxy near the Southern Cross; but this did not last long, although the general appearance was continued for more than half an hour, with varying play of light, over a space of about 140° of the southern heavens, with pretty well-defined eastern and western boundaries of deep rose colour, culminating in the white focus near the Pleiades, which appeared the centre of action. The rose colour was chiefly confined to the eastern and western boundaries, with intermittent starts of whitish radiation toward the south. Occasionally well-defined streaks of a lighter tint crossed the western portion of the rose cloud, which appeared to originate from the light of the sun, now, of course, far below the horizon. At length the eastern portion became less brilliant, but still Orion was enveloped in a steady rose haze, although it gradually became fainter, until, a little before 7 o'clock, the rose colour below Orion toward the eastern horizon became as brilliant as ever, and soon a straight broad ray of rose colour started up from the horizon. This was not curved or arched, like the whiter radiations which seemed to originate from near the zenith; nor was it, like them, intermittent and wavy; but had the appearance of a broad beam of rose light originating below the horizon, and darting straight upward in a diagonal direction, proceeding over Castor and Pollux and Jupiter. Then the north side of this became of a peculiar light bluish green; if I may be allowed to coin a word, it was of a moonshiny colour. If the moon had been a few days younger, I should have thought it originated from the

moon. This very peculiar and distinct broad beam or bar of light almost developed prismatic colours from its southern rose edge, to its northern bluish-green well defined border. There was also a somewhat indistinct tendency to the same prismatic appearance, spreading some little distance over the heavens on the south side of this beam near the zenith. The northern segment of the sky from Castor and Pollux to about direct west was still perfectly clear, both from cloud and aurora, right down to the horizon; there was a bank of cloud along the southern horizon. About 7 o'clock there was an appearance of rose tint to the north of the peculiar straight beam spoken of, and this reached as far as the pointers in the Great Bear. About the same time there was a peculiar development of white cloud from the zenith toward the north-west, streaked and fringed with well defined radiations, and this gradually increased until the northern portion of the heavens, which had hitherto been quite clear, was covered to within 30° of the horizon, the border of this cloud being very distinctly and deeply serrated with fan-like shapes radiating from near the zenith. The phenomena I have described occupied more than an hour, and my attention was now drawn from it until after 8 o'clock, when the whole heavens were cloudy, but behind and between the clouds the rose tint was still visible as an irregular arch stretching from north to west. As the clouds broke off the whitish wavy radiation could be occasionally seen still issuing from near the zenith, and across the western part of the rose arch were occasionally seen the straight diagonal bars of a brighter shade, apparently caused by the light of the sun, but the clouds obscured most of the phenomena. At a last look near 9 o'clock the clouds had somewhat cleared, and there were two brilliant arches, more like the regular aurora from the north-west horizon towards the zenith, at right angles to the more cloudy arch, which had been visible for some time stretching from the north to the west.

W. SYMONS

Barnstable, Feb. 5

LAST evening (Sunday, February 4) the sky presented a weird and unusual aspect which at once struck the eye. A lurid tinge upon the clouds which hung around suggested the reflection of a distant fire, while scattered among these torn and broken masses of vapour having a white and phosphorescent appearance, and quickly altering and changing their forms, reminded me of a similar appearance preceding the great aurora of October 1870. Shortly some of these shining white clouds or vapours partly arranged themselves in columns from east to west, and at the same time appeared the characteristic patches of rose-coloured light which are seen in an auroral display.

About 8 o'clock the clouds had to a certain extent broken away, and the aurora shone out from behind heavy banks of clouds which rested on the western horizon, the north-eastern horizon being free from cloud and shining brightly with red light. And now, at about 8.15, was presented a most beautiful phenomenon. While looking upwards I saw a stellar-shaped mass of white light form in the clear blue sky immediately above my head, not by small clouds collecting, but apparently forming itself in the same way as a cloud forms by condensation in a clear sky on a mountain top, or a crystal shoots out in a transparent liquid, leaving, as I fancied, an almost traceable nucleus or centre with spear-like rays projecting from it; and from this in a few seconds shot forth diverging streamers of golden light, which descending met and mingled with the rose patches of the aurora hanging about the horizon. The spaces of sky between the streamers were of a deep purple (the effect of contrast), and the display, though lasting a few minutes only, was equal if not excelling in beauty, though not in brilliancy, the grand display in 1870, before alluded to, in which latter case, however, the converging rays form in a ring or disc of white light of considerable size.

What struck me particularly was the aurora developing itself as from a centre in the clear sky, and the diverging streamers apparently shooting downwards, whereas in the ordinary way the streamers are seen to shoot up from the horizon and converge overhead. The effect may have been an illusion, but if so it was a very remarkable one. Examined with one of Mr. Browning's direct seven-prism spectroscopes, I saw the principal bright line in the green everywhere (the other lines were not visible), and noticed the peculiar flickering in that line which I noticed in 1870, and which has also I think been remarked by Sir John Herschel. The general aurora lasted for some time till lost in a cloudy sky, and in fact rain was descending at one time while the aurora was quite bright. Strong wind prevailed during the

night. The aurora was probably extensive, as the evening, notwithstanding the clouds, was nearly as bright as moonlight.

Guildford, Feb. 5

T. RAND CAPRON

The Floods

Two of the largest districts which are most constantly flooded are, perhaps, Oxford and "The Plain of York." The same cause floods both these districts, namely, what Mr. Mackintosh has called "Colonel Greenwood's hard gorge and soft valley theory." Both these districts have been worn down by rain and rivers in the soft oolitic strata; and the Humber and the Thames have ever had, and have now, to force outlets through comparatively hard chalk gorges. The rain-flood waters, checked at these gorges, overflow and deposits alluvium behind the gorges. The same takes place in the soft strata of the Weald, behind the nine comparatively hard chalk gorges of the North and South Downs.

Brookwood Park, Alresford, Feb. 3

Zodiacal Light

THE evening of Feb. 2 being clear, after a long persistence of rainy cloud for many days, about 6.5 P.M. I began to notice the existence of a zodiacal light. Some time later, probably about 6.40, it was considerably brighter than any portion of the galaxy in sight at the time, though this might not have been the impression of an inattentive spectator, as the gradual melting away of its edges produced much less contrast with the ground of the sky than the better defined outline of the Milky Way. Its light was, in fact, so imperceptibly diffused that it was impossible to fix its boundaries or extent with any accuracy. Its general position was, however, undoubtedly a little below the square of Pegasus (where its upper edge fell short of α and γ), and beneath the three stars of Aries; but its light was here so enfeebled that its termination was quite uncertain, and it could only be said that the direction of its axis was towards the Pleiades. Its breadth where most brilliant, near Pegasus, might probably be estimated at 8° or 9° , from comparison with the distance from α to β , and with the length of the belt of Orion; but this determination was liable to great uncertainty. It was thought to show a ruddy tinge, not unlike the commencement of a crimson Aurora Borealis; this may have been a deception, but it was certainly redder or yellower than the galaxy. At 7 I examined it with a little pocket spectroscope, which shows very distinctly the greenish band of the aurora; but nothing of the kind was visible, nor could anything be traced beyond a slight increase of general light, which, in closing the slit, was extinguished long before the auroral band would have become imperceptible. It was still visible at 8.30. The phenomenon had been previously noticed, but with less distinctness, on Dec. 30 and Jan. 11.

Magnetic Disturbance during Solar Eclipse

WITH the known relation existing between the sun and terrestrial magnetic disturbance, it is not surprising that some indication of a change in the earth's magnetism might be expected during a solar eclipse; and the case cited by the Rev. S. J. Perry, of its supposed observation by M. Lion, is not the first instance of the kind.

Shortly after the eclipse of 1870, Signor Diamilla Müller, of Florence, published a paper in the *Gazzetta Ufficiale*, No. 17, describing some magnetic observations made in Italy during the 21st, 22nd, and 23rd December, and from which it appeared that there was a slight variation in the curve of the 22nd, at the time of the eclipse, which did not appear in the curves of the preceding and subsequent days. Signor Müller at once concluded that the variation was produced by the eclipse; but it was pointed out by Senhor Capello, of the Lisbon Observatory, that the same disturbance was recorded by his self-recording instruments, but it occurred there some time before the totality. It was also recorded by the instruments here, and proved to be insignificant when compared with other disturbances continually observed.

A careful examination of the curves for the time of the 1860 eclipse has also failed to show any trace of a similar movement then occurring.

Circumpolar Lands

MR. HAMILTON, in NATURE of January 25, refers to a paper in which "the rising of the land at the poles is inferred as a necessary result of the cooling and contracting of the earth." He then goes on to give the substance of part of the paper, beginning as follows:—

"If a spheroid of equilibrium, in motion about an axis, contract uniformly in the direction of lines perpendicular to its surface, a new spheroid is produced, having a greater degree of eccentricity, because if equal portions are taken off the two diameters, the ratio of the equatorial diameter is increased. This is equivalent to a heaping up of matter around the equator."

The reasoning of this latter passage appears sound, but it contradicts the former one. As I have shown in my letter to which Mr. Hamilton replies, the facts, so far as known, appear to point to a relative increase of the polar diameter; he admits this, and then gives reasons for expecting a relative increase of the equatorial one. He must have made some oversight.

Old Forge, Dunmurry, Jan. 27 JOSEPH JOHN MURPHY

THE HISTORY OF PHOTOGRAPHY

I TRUST you will kindly allow me space for a few lines on the subject of some rare specimens connected with the History of Photography, now in the possession of Madame Niépce de St. Victor, whose husband it will be remembered was the first to employ glass, and a transparent medium (albumen) for the purposes of photography, thus discovering, to a great extent, the process of Photography as it exists at the present day. The first glass negative, or rather *éclaté*, Madame Niépce possesses, as likewise prints executed in 1848.

Niépce de St. Victor was likewise one of those who have worked hard to secure *natural colours* in the camera, some very perfect specimens—photographs of coloured dolls—which prove distinctly that the solution of the problem is not impossible, as many believe, are also included in the Niépce collection, together with some results of early photo-engraving.

Madame Niépce and family have been left, I regret to say, in very straitened circumstances, for the busy philosopher in his lifetime had but the pay of a subordinate officer in the French Army to subsist on. She has placed in the possession of the Photographic Society this valuable collection of her late husband, and it is proposed to exhibit it at the next meeting of the Society on the 13th inst., and any institution or individual desiring to become possessed of some of the specimens will be readily furnished with information by

H. BADEN PRITCHARD

GANOT'S PHYSICS*

GANOT'S Physics is so well known in this country that our task is very different from that of reviewing a new work, and we can do little more than compare this edition with the previous. It is unusual for any large scientific work to pass through five editions in about ten years, and the value of the book may be estimated by this fact. It has passed through more than twice the above number of editions in France, and has been translated into various European languages. In the present edition the type has been altered, and the size of the page somewhat increased, while twenty-eight new illustrations have been added, and the text has been augmented.

The doctrine of energy has of late been so largely developed that we are surprised to find so small an amount of space given to the subject. No more than two pages are devoted to it, while the term "transmutation of energy," does not appear in the index. Neither do we find the terms "Kinetics" and "Kinematics;" yet we imagine that the student who presented himself as a candidate for a Science Scholarship at any of our Uni-

* An Elementary Treatise on Physics, Experimental and Applied. Translated and Edited from Ganot's "Éléments de Physique," by E. Atkinson, Ph.D., F.R.S. Fifth Edition, Revised and Enlarged, 828 pp. 8vo. (London: Longmans and Co. 1872.)

versities, not knowing the meaning of these terms, might find himself quite at sea in some of the questions. In-

FIG. 1.

FIG. 2.

deed we do not find much introduction of the terms of the Thomsonian Physics, and this is surely to be re-

gretted; for just as the philosophy of Francis Bacon used to be called the "New Philosophy," so might the Natural Philosophy developed in the treatise of Tait and Thomson be called the "New Physics." The experimental science of the future must be based, we conceive, upon the system therein elaborated.

We are glad to notice a very good account of Morin's apparatus for demonstrating the laws of falling bodies (p. 49), which does not appear in the 1868 edition. The principle of this, it will be remembered, is to cause a falling body to trace its own path upon a rotating cylinder. The accompanying diagram (Figs. 1, 2) needs no explanation. The vanes are for the purpose of producing uniformity of motion in the revolving cylinder; the falling weight is a mass of iron, P, furnished with a pencil, which presses against the paper on the revolving cylinder. The curve traced can be proved to be a parabola, and the paths

FIG. 3.

FIG. 4.

traversed in the direction of the descent are shown to vary directly as the squares of the lines in the direction of rotation.

Under the head of "Endosmose of Gases" (p. 97) we find no account of the cause of diffusion of gases, the experiments of Graham, the determination of the relative velocity of atoms by Clausius, and the explanation of such facts as the rate of diffusion of hydrogen being four times greater than that of oxygen. But it may be argued that this rather belongs to Chemistry.

We are glad to see that the law which relates to the volume of gases under varying pressures is now called after its true discoverer, "Boyle's Law," but the experiment, demonstrating at once the incompressibility of fluids and the porosity of dense bodies, is, as usual, attributed to the members of the Accademia del Cimento, while it was in reality proved twenty years earlier with

a hollow sphere of lead by Francis Bacon. Again "Mariotte's Tube," as it is called (p. 120), is described and figured by Robert Boyle fourteen years before Mariotte mentions it. Morren's mercury pump for slow but accurate exhaustion is described and figured on p. 141 (Figs. 3, 4); by its means a vacuum of one-tenth of a millimetre of mercury may be obtained.

The Acoustics has been considerably augmented, for while in the 1868 edition it occupied fifty-two pages, it now fills fifty-five larger pages. We notice, among other things, an account and woodcut of König's stethoscope, and of his cylindrical resonator; of Helmholtz's apparatus for the synthesis of sounds; and various new woodcuts of manometric flames. We do not observe any mention of singing or sensitive flames. In the section devoted to heat, we do not find an account of Prof. Guthrie's experiments on the conduction of heat by liquids; or of the recent observations regarding the heat of the moon and certain stars; and the portion relating to the "Mechanical Equivalent of Heat" is still very meagre and insufficient.

The magnetism of iron ships might with advantage be alluded to in the account of Magnetism; and M. Noë's very powerful thermo-electric battery is also worthy of notice. On pp. 596 and 597 we are glad to observe capital figures and descriptions of the electrical machines of Bertsch and Carre; the latter appears to be a most desirable addition to the Physical Laboratory, as, even without a condenser, plates of 49 centimetres diameter give sparks 18 centimetres long, and the machine is not much affected by moisture. The apparatus figured on pp. 678—679 for demonstrating the attraction and repulsion of electric currents by currents, consists of new and improved forms of those devised by Ampère, and is extremely ingenious; as is also the form of solenoid described on p. 690. (Fig. 5.)

FIG. 5.

A few alterations in the text would be advisable if a table of errata is introduced; thus (p. 750) no explanation is given of the stoppage of a cube of copper when caused to rotate between the poles of a powerful electro-magnet, as soon as the magnet is made; neither is reference given to the explanation which in another form is given elsewhere. Again (p. 628) we read:—"Kirchhoff has concluded that the motion of electricity in a wire in which it meets with no resistance is," &c. A very few clerical errors are observable:—p. 185, M. Costa should be M. Corti; p. 246, topmost line, "substances by which their action," &c., should read "which by their action;" p. 289, line ten from the top, β should be β' ; and p. 524, line 4, we find "plain polarised light."

These, however, are quite minor matters; the book was a good one at the outset of its career, and each succeeding edition has rendered it more and more complete. The above remarks are made rather as suggestions than in any spirit of adverse criticism. Ganot's Physics is a great addition to our scientific literature, and neither student nor *savant* could spare it from his library.

G. F. RODWELL

THE SOLAR ATMOSPHERE

THE object of the investigation discussed in NATURE (No. 101, pp. 449-452) being merely that of ascertaining whether the incandescent matter contained in the solar atmosphere transmits radiant heat of sufficient energy to admit of thermometric measurement, no particular statement was deemed necessary regarding the spectrum which appeared on the bulb of the focal thermometer after shutting out the rays from the photosphere

during the experiments. The appearance of this spectrum has in the meantime been carefully considered. Its extent and position suggest that the depth of the solar atmosphere far exceeds the limits hitherto assumed.

The accompanying illustration represents an apparatus constructed by the writer to facilitate the investigation. Evidently the expedient of shutting out the photosphere while examining the effect produced by the rays emanating from the chromosphere calls for means by which the sun

may be kept accurately in focus during the period required to complete the observations. The main features of the apparatus being shown by the illustration, a brief description will suffice. The parabolic reflector which concentrates the rays from the chromosphere (described in the previous article) is placed in the cavity of a conical dish of cast-iron, secured to the top of a table suspended on two horizontal journals, and revolving on a vertical axle. The latter, slightly taper, turns in a cast-iron socket which is bushed with brass and supported by three legs stepped on a triangular base, resting on friction-rollers. The horizontal journals referred to turn in bearings attached to a rigid bar of wrought-iron situated under the table, firmly secured to the upper end of the vertical axle. The horizontal angular position of the table is adjusted by a screw operated by the small hand-wheel *a*, the inclination being regulated by another screw turned by the hand-wheel *b*. A graduated quadrant, *c*, is attached to the end of the table in order to afford means of ascertaining the sun's zenith distance at any moment. The index *d*, which marks the degree of inclination, is stationary, being secured to the rigid bar before described. The rays from the photosphere are shut out by a circular disc, *f*, composed of sheet metal turned to exact size, and supported by three diagonal rods of steel. These rods are secured to the circumference of the conical dish by screws and adjustable nuts in such a manner that the centre of the disc *f* may readily be brought in a direct line with the axis of the reflector. The mechanism adopted for adjusting the position of the table by the hand-wheels *a* and *b* requires no explanation; but the device which enables the operator to ascertain when the axis of the reflector is pointed exactly towards the centre of the sun demands particular notice. A shallow cylindrical box, *g*, provided with a flat lid and open at the bottom, excepting a narrow flange extending round the circumference, is firmly held by two columns secured to the top of the table. A convex lens of 26 inches focus is inserted in the cylindrical box, the narrow flange mentioned affording necessary support. The lid is perforated by two openings at right angles, 0.05 inch wide, 2.5 inches long, forming a cross, the lens being so adjusted that its axis passes through the central point of intersection of the cross. The face of the table being turned at right angles to the sun, or nearly so, it will be evident that the rays passing through the perforations and through the lens will produce, at a certain distance, a brilliantly illuminated cross of small size and sharp outline. A piece of ivory, or white paper, on which parallel lines are drawn intersecting each other at right angles, is attached to the top of the table in such a position that the centre of intersection of the said lines coincides with the axis of the lens. This axis being parallel with the line passing through the centre of the disc *f* and the focus of the reflector, it will be perceived that the operator, in directing the table, has only to bring the illuminated cross within the intersecting parallel lines on the piece of ivory. Ample practice has shown that by this arrangement an attentive person can easily keep the disc *f* accurately in line with the focus of the reflector and the centre of the sun during any desirable length of time. The absence of any perceptible motion of the column of the focal thermometer during the experiments which have been made furnishes the best evidence that the sun's rays have been effectually shut out by the intervening disc, which, it should be remembered, is only large enough to screen the aperture of the reflector from the rays projected by the photosphere. It may be noticed that actinometric observations cannot be accurately made unless the instrument is attached to a table capable of being directed in the manner described; nor is it possible to measure the dynamic energy transmitted by solar radiation unless the calorimeter employed for the purpose faces the sun with the same precision as our parabolic reflector. It is worthy of notice that the lightness of the illustrated apparatus ren-

ders exact adjustment easy, since screws of small diameter and fine pitch may be employed. It only remains to be stated that in order to admit of accurate examination of the spectrum before referred to, the thermometer is removed during investigations which do not relate to temperature, a cylindrical stem of metal, 0.25 inch diameter, coated with lamp-black, being introduced in its place.

With reference to the result of recent experiments, it is proper to state that, at the present time, the sun's zenith distance being now nearly 60° at noon, no perceptible heating takes place in the focus of the parabolic reflector. The observations relating to temperature mentioned in the previous article, were made when the zenith distance was only one-third of what it is at present. The consequent increase of atmospheric depth, at this time, has completely changed the colour of the spectrum, and rendered the same so feeble that its extent cannot be determined. As seen last summer, before the earth had receded far from the aphelion, the termination of the spectrum reached so far down that an addition of 0.15 inch to the radius of the disc *f* would scarcely have shut it out. Now an addition of 0.15 inch to the radius of the disc corresponds to an angular distance of $9' 45''$; hence, assuming the radius of the photosphere to be 426 300 miles, the depth of the solar atmosphere cannot be less than 235 000 miles. And, judging from the appearance at the period referred to, there can be little doubt that a larger and more perfect reflector will enable us to trace the spectrum still further down. Consequently, a further enlargement of the disc *f* will be required to extinguish wholly the reflected light from the solar atmosphere. It is reasonable, therefore, to suppose that the depth of the solar atmosphere will ultimately be found to exceed very considerably the foregoing computation.

It has been suggested regarding the instituted investigations of the radiant heat transmitted by the chromosphere, that the thermo-electric pile ought to be employed in combination with the parabolic reflector. The object of the investigation being simply that of proving by the feebleness of the radiant power transmitted to the surface of the earth that the chromosphere and outer strata of the sun's envelope do not possess radiant energy of sufficient intensity to influence solar temperature as supposed by Secchi, tests of the suggested extreme nicety are not called for.

With reference to the effect of increased depth, the small amount of retardation suffered by the rays in passing through the highly attenuated atmosphere of the sun, previously established, shows that the question of solar temperature will not be materially affected, even should it be found that the depth of the envelope is greater than the radius of the photosphere.

J. ERICSSON

THE RIGIDITY OF THE EARTH

SIR WILLIAM THOMSON'S views regarding the rigidity of the earth have been hitherto received in silence by those who entertain different opinions from him; but it does not follow on this account that they regard his position as unassailable. It is more satisfactory to attempt to establish positive results in science, than to criticise the labours of others; but as Sir William Thomson, by his letter in *NATURE* for January 18, manifestly invites discussion, I hope I shall be excused for making the following remarks.

When nearly ten years since I saw the abstract in the Proceedings of the Royal Society which he appends to his letter, I resolved to suspend my judgment until I had an opportunity for reading his papers *in extenso*. To such of your readers as happen to be interested in this question, and who have not yet seen these publications, I would venture to recommend a similar course. In the

"Philosophical Transactions" for 1862, the memoir on the rigidity of the earth is fully printed, and immediately following it is another designated "dynamical problems regarding elastic spheroidal shells and spheroids of incompressible liquid." The conclusions arrived at in the first are essentially and admittedly dependent on the investigations presented in the second. Not long after they were published I gave my best attention to the study of both, and it soon appeared to me that the problems treated in the second could have no physical bearing on the question of the earth's structure. The very title of this memoir partly reveals its character in this respect. In order to apply the results obtained in this memoir to the earth, it is supposed to be a spheroidal homogeneous elastic shell filled with incompressible fluid; whereas in such an inquiry the earth can scarcely be supposed to be otherwise than a heterogeneous solid envelope containing a fluid whose properties are not inconsistent with those of fluids coming under our notice. Under this form I have treated the hypothesis in the "Philosophical Transactions" for 1851, and also in subsequent publications.

Incompressibility is not a property of any known fluid; and Neumann, when referring in his comprehensive treatise on geology to the influence of pressure in promoting the density of the interior parts of the earth, expresses what is very generally admitted among philosophical geologists as well as physical inquirers, when he says that "fluid bodies are endowed with *far more* compressibility than solids."* Hypotheses are often indispensable in physical inquiries where we are proceeding from the known to the unknown, but there are two conditions to which they should conform; first, they should be capable of verification by a comparison of the results to which they lead with those of observation, and secondly, they should not contradict established physical laws or the known properties of matter, unless the contradiction is specially explained and fully accounted for. The second of these conditions is clearly violated when the internal fluid of the earth is supposed to differ from all known fluids by being supposed to be incompressible. And this violation is especially flagrant when the solid matter enclosing the incompressible fluid is supposed to be at the same time elastic and therefore compressible, and when, moreover, the line of reasoning adopted as to the earth's internal structure pointedly depends upon these assumptions as to the properties of its fluid and solid portions. Sir William Thomson endeavours to prove, by a process of *reductio ad absurdum*, that the interior of the earth is for the most part or altogether solid; in other words, he supposes the interior to be fluid, and then tries to show that the tidal actions produced in this fluid by the sun and moon must cause oscillations in the crust which have not been observed. He may justly claim to have proved that the earth does not consist of an elastic solid envelope enclosing a mass of the ideal substance called an incompressible liquid, but he has not proved the point which he intended to establish, namely, the absence of an interior fluid nucleus endowed with the properties commonly attributed to fluids. He also supposes throughout his investigations, in the same manner as was supposed by Mr. Hopkins, that the transition from the solidity of the shell to the fluidity of the nucleus is not gradual but abrupt. Those who maintain the validity of the hypothesis of the interior fluidity of the earth are far from holding this opinion. On the contrary, all observations hitherto made on the materials of the earth lead to the conclusion that the solid shell is so constituted as to present first a superficial coating whose mechanical properties we can partly ascertain by direct experiment; secondly, a mass whose density and rigidity probably increase with the depth from the outer surface; thirdly, an interior coating in which the effects of pressure are resisted by those of temperature, and where an imperfectly

fluid and pasty mass is in contact at one side with the solid shell, and on the other with the more perfect fluid. This mass should be manifestly much more yielding and compressible than the perfectly solidified shell; for if compression tends to increase the rigidity of solid matter, the middle division of the shell, as just described, should be more rigid than its superficial portion, and very much more rigid than the interior pasty mass. The work performed by small changes of shape in the fluid nucleus due to the action of exterior disturbing bodies should thus be expended partly in producing small variations of density among the compressible strata of which it is composed, and partly in changing the shape of the yielding matter of the inner surface of the shell. The deformations of a shell consisting of homogeneous elastic matter, such as steel acted upon by exterior forces, must be the resultants of all the elementary deformations among its particles summed up or integrated. It would behave somewhat like a vibrating bell; but such is not the behaviour to be expected in a mass of discontinuous and heterogeneous materials. Vibratory motions in such bodies are for the most part extinguished by interferences, or their amplitudes are at least very much reduced.

If the conclusions deduced by M. Perrey of Dijon from his voluminous labours so often referred to by Mr. Mallet in his Reports on Earthquakes, be correct, some connection between these disturbances and the phases of the moon seems to be established which may be due to such comparatively feeble vibratory actions. Sir William Thomson's conclusions rightly interpreted show that the constitution of the fluid nucleus and the nature of the materials of the shell must be essentially different from what he supposes in order to establish these conclusions. A person who never saw a railway train might as justly reason as to the impossibility of travelling in it at high rates of speed, by demonstrating that the shocks experienced by perfectly rigid carriages connected without any compressible arrangements would be too great for travellers to endure, if not too great for the permanent integrity of the carriages themselves. In assuming the incompressibility of the fluid nucleus for the purposes of his indirect demonstration of the rigidity of the earth, Sir William Thomson makes a *petitio principii* nearly as vital as shocks incident to influence of buffers in reasoning on the omission of the railway carriages.

I am at a loss to know where any warrant was found for affixing the property of incompressibility to the supposed fluid nucleus of the earth; and those who maintain the hypothesis of the interior fluidity of the earth are entitled to repudiate an assumption fastened on that hypothesis not only in opposition to evidence derived from experiments on fluids, but in direct contradiction to the arguments employed by them in discussing the question of the earth's structure.

HENRY HENNESSY

THE LANDSLIPS AT NORTHWICH

IN the "Notes" of the number of NATURE, for Jan. 25, I find one referring to the landslips at Northwich in Cheshire, by mistake called Nantwich. As the description given of these landslips and their cause is scarcely accurate, your readers may like to see a short account of them.

Northwich is the great centre of the Cheshire salt trade. The manufacture is principally carried on now at Northwich and Winsford, both towns lying in the valley of the River Weaver, though formerly Nantwich was engaged in this trade, and Middlewich still continues so to be. The position of the latter is indicated by its name, it lying between Northwich and Nantwich. The salt is found lying in two beds, called the upper and lower rock salt. The first bed is met with in the neighbourhood of Northwich at the depth of about forty yards, and

* Lehrbuch der Geologie, i. p. 268, 2nd edition.

is twenty-five yards thick. Although brine springs had been known and worked as early as the time of the Norman Conquest or earlier, yet the bed of rock salt was only discovered in 1670 when searching for coal at Marbury, about a mile to the north of Northwich. During the last 200 years this rock salt has been worked, or to speak more correctly, for more than a century the upper bed was worked, when an agent of the Duke of Bridgewater sank lower still, and, after passing through about ten yards of hard clay and stone, with small veins of rock salt running through it, the lower bed of rock salt was discovered. This lower bed is between thirty and forty yards thick, but only about five yards of the purest of it is "got." This good portion lies at a depth of from 100 to 110 yards, according to the locality. In the neighbourhood of Winsford both beds are met with at a much greater depth. The whole of the rock salt obtained is got now from the lower bed, and last year it reached nearly 150,000 tons, probably the largest quantity ever obtained in one year. It may as well be said that this mining of rock salt has had nothing whatever to do with the subsidences spoken of, though the wording of the note would lead readers to expect the contrary. At present there is no danger to be expected from the lower bed of rock salt. The whole danger arises from the upper bed, as will be seen from the following account:—The salt trade of Cheshire is a very extensive one, and during the year 1871 upwards of 1,250,000 tons of white salt have been sent from the various works in that county. The whole of this immense quantity has been manufactured from a natural brine which is found in and around Northwich and Winsford, as well as in several other smaller places. This brine is produced by fresh water finding its way to the surface of the upper bed of rock salt, technically called the Rock Head. The fresh water dissolves the rock salt, and becomes saturated with salt. The ordinary proportion of pure salt in the brine is 25 per cent. To obtain the quantity of salt above mentioned, it would be necessary to pump 5,000,000 tons of brine. The pumping of brine is incessantly going on, and as a natural consequence the bed of rock salt is being gradually dissolved and pumped up. As the surface of the salt is eaten away, the land above it subsides. This subsidence is not spread over the whole surface, but seems to follow depressions in it, thus forming underground valleys with streams of brine running to the great centres of pumping. Wherever a stream of brine runs, there the subsidence occurs, and in many localities the sinking is very rapid and serious, but fortunately is almost always gradual and continuous. An immense lake, more than half a mile in length, and nearly as much in breadth, has been formed along the course of a small brook that ran into the river Weaver, and this lake is extending continually. Besides this gradual continuous sinking, which affects the town of Northwich very seriously, causing the removal and rebuilding of houses or the raising of them by screw-jacks in the American fashion, the raising of the streets and so on, there is a sudden sinking of large patches of ground, leaving large deep cavities such as described in your Note. These latter are more terrifying and dangerous. They are in the majority of cases caused by the falling-in of old disused mines in the upper bed of rock salt. These old mines were worked so as to leave but a thin crust of rock salt between the superincumbent layers of earth and the mines. The roof of the mine is supported by pillars of rock salt at intervals. Of course the weakest and most dangerous point is the old filled-up shaft. As most of these mines have been disused for nearly a century, the position of the old shafts is unknown. When the brine has eaten away the layer of rock salt left as a roof, the whole of the earth lying above falls into the mine, and an enormous crater-like hole, some 100 feet or more in depth, is formed, which in process of time becomes filled up with water, the mine itself being choked with earthy

matter. In the immediate neighbourhood of Northwich there are a great number of these rock pit holes, as they are called, and it is nothing very unusual for one to fall in.

The rock miners, as they are called, were at work in the lower mine last year when one of these sudden subsidences occurred. They knew nothing of it. I have been myself under this hole, and it was a fearful one to look at when it first went in. There is no communication between the upper and lower beds, and the miners have about thirty yards of hard clayey stone and rock salt between them and the upper old mines. The subsidence more particularly alluded to in your Notes is not in the immediate neighbourhood of Northwich, but rather midway between Northwich and Winsford, near Marton Hall. It is rather difficult to know what is its cause, as there is no record of any mines ever being worked in that neighbourhood. The general belief is that the rock salt, which undoubtedly underlies the whole neighbourhood, has been gradually dissolved, and that a sinking has commenced as at Northwich; then that, owing to some peculiarity of the particular overlying strata—probably to their sandy nature, as quicksands are known to exist about Northwich—the earthy and sandy matter of the immediately overlying strata has been carried away by the brine streams till a large hollow has been formed. This has continued till the superincumbent mass could not be borne up any longer, and thus suddenly fell in, filling up the lower cavity, but opening a large crater-like pit from the surface.

A Government inspector has been to the neighbourhood, and his report is expected very shortly.

The whole neighbourhood of Northwich is well worthy of more attention than it has received, and it is surprising that our geologists have not been able to give a better account of the rock salt formation than has yet been done.

THOS. WARD

NOTES

WE are glad to be able to state that the severe sentence passed upon M. E. Reclus has been changed, in consequence of the representations of the scientific men of this and other countries, into the comparatively mild one of exile from France.

WE understand that the Chair of Anatomy in the new German University of Strasburg has been offered to, and declined by, Prof. Gegenbaur, who has done so much to raise the scientific reputation of the University of Jena. A similar offer has also been made to Gegenbaur's distinguished colleague, Haeckel, the result of which is not yet announced.

THE Master and Senior Fellows of St. John's College, Cambridge, have elected Mr. J. B. Bradbury, M.D., of Downing College, Linacre Lecturer in Medicine in the room of Dr. Paget, who has been elected Regius Professor of Physics.

THE Royal Commission on Scientific Instruction and the Advancement of Science recommenced their sittings yesterday.

THE two Smith's Prizes of the University of Cambridge have been this year awarded to the First and Second Wranglers respectively.

WE regret to learn that the Australian Eclipse Expedition has proved a failure, through the unfavourable state of the weather at the point of observation.

IT is with great regret we have to record the death on Wednesday, January 31, at Torquay, of Dr. G. E. Day, F.R.S., late Chandos Professor of Medicine in the University of St. Andrew, at the age of 56. Our columns have borne frequent evidence of the extent of Dr. Day's acquirements in many branches of

Natural History. He was one of the founders of the Pathological and Cavendish Societies.

THE name of Colonel Chesney, F.R.S., of the Royal Artillery, who died on Tuesday, the 30th ult., at his residence near Killeel, Co. Down, Ireland, in the 83rd year of his age, was almost more familiar to the last generation than to this. Among his various titles to eminence as traveller, *seaman*, and military critic, he will be chiefly known as "the pioneer of the overland route to India." It is now nearly forty years since General, then Captain, Chesney returned from his explorations of the Euphrates for the purpose of establishing steam communication with India *via* Egypt and Asia Minor, to ask the Government to give him the command of an expedition. The demand was granted; two vessels, the *Tigris* and the *Euphrates*, were placed at his disposal. The indefatigable manner in which he prosecuted his scheme, in the face of many disappointments and discouragements, is well known. He has himself written the history of his travels and adventures; and the lines of communication now in existence bear witness to the practical value of his projects. General Chesney has for many years back enjoyed the repose which was the fitting reward of much arduous toil; and now leaves behind him the record of a useful, honourable, and well-spent life.

DR. WILLIAM BAIRD, F.R.S., whose death we recorded last week, after a long and painful illness, was born at Eccles, in Berwickshire, in the year 1803, educated at Edinburgh, and received in 1823 an appointment as surgeon from the East India Company. While in this office he visited India, China, and many other countries, the natural history of which he carefully studied. In 1831 he published a paper "On the Luminosity of the Sea," in *Louison's Magazine of Natural History*, and from that time became a frequent contributor to the scientific journals, more especially to the "Transactions" of the Berwickshire Naturalists' Club. In 1838 he compiled a Cyclopædia of the Natural Sciences. In September 1841 he was appointed an Assistant in the Zoological Department of the British Museum, which office he filled till his death. In 1851 his monograph on the British Entomostraca Crustacea, a work of great ability and research, was published by the Ray Society. Between the years 1838 and 1863 he contributed a number of papers on the Entomostraca to the "Annals of Natural History," and the "Proceedings" of the Zoological Society. During the latter years of his life his attention was principally given to the Entozoa, of the then known species of which he had as early as 1843 drawn up a catalogue, which was published by the trustees of the British Museum. Numerous papers on the same subject were also contributed by him to the "Proceedings" of the Zoological Society, the "Transactions" of the Linnean Society, &c. Latterly he was engaged in preparing a general catalogue of the Entozoa, for which he had accumulated a vast amount of material. His knowledge of some other branches of natural history was equally extensive and profound, and his death will leave a gap among those who were acquainted with his varied acquirements, and the courtesy and readiness to assist displayed to all who sought his help or advice.

THE *Academy* records the death of Prof. Trendelenburg, of Berlin, who had attained a two-fold eminence as a philologist and Aristotelian commentator, and as an original thinker.

THE Waynflete Professorship of Chemistry at the University of Oxford, will shortly become vacant by the resignation, through ill-health, of Sir Benjamin Collins Brodie, Bart., M.A. The Waynflete Professorship of Chemistry was directed by the ordinance of the University Commissioners of 1854, relating to Magdalen College, to be founded in that college in lieu of certain prebendalities mentioned in its ancient statutes, and to be maintained by a stipend of 600*l.* per annum. The Professor is elected by the Chancellor of the University, the

Visitor and President of the College, and the Presidents of the Royal Society and of the College of Physicians. Prof. Brodie was elected in 1865, and was the first professor under the new ordinance, having previously resigned the Aldrichian Professorship of Chemistry, which he had held since the resignation of the late Dr. Daubeny, and which chair was suppressed in 1866, the revenues being applied to the payment of a salary of a Demonstrator, and to the purchase of chemical apparatus or other means towards the study of chemistry in the University.

IN the *Gazette of India* is the following tribute to the memory of the late Archdeacon Pratt:—"The Governor-General in Council has received with deep regret official intimation of the death of the Venerable the Archdeacon of Calcutta, the Reverend J. H. Pratt, on the 28th ultimo, at Ghazepore, in the North-Western Provinces. The Governor-General in Council cannot allow the death of Archdeacon Pratt to pass unnoticed by the Government which he served so long and so well. Mr. Pratt entered the service in the year 1838, and was appointed Archdeacon of Calcutta by the late Bishop Wilson on the 6th October, 1849. Under the ordinary rules of the service, Mr. Pratt would have retired in October, 1867, but so efficiently had he filled his high office in the Church, that he was solicited by Government, with the full approval of Her Majesty's Secretary of State, to continue to hold it. In adopting this course the Government was moved not only by its own appreciation of the Archdeacon's services, but the strong recommendation of the late Bishop Cotton, whose bare testimony to Archdeacon Pratt's eminent scientific attainments and university distinctions, to the active part which he had taken in the management of the diocese, and in the promotion of all good works, and to his personal piety and high Christian character. At a later date Her Majesty's Secretary of State, in sanctioning the retention of Archdeacon Pratt in the service until October 1872, remarked:—'I cannot refrain from expressing the high sense I entertain, in common with the present Bishop of Calcutta, the Lieutenant-Governor of Bengal, and your Excellency in Council, of the zeal and ability with which he has for so many years faithfully and laboriously discharged the duties of his Office.' The Governor-General in Council feels assured that the death of the Venerable Archdeacon will be mourned by the entire Christian community in India."

IT is announced that Professor Flower will commence his annual Hunterian Lectures on Comparative Anatomy in the Theatre of the Royal College of Surgeons on Friday, the 16th inst., at four o'clock. The lectures will be continued at the same hour every Monday, Wednesday, and Friday until the 27th of March. The subjects to be embraced by the present course are the modifications of the organs of digestion, including the mouth, tongue, salivary glands, alimentary canal, liver, and pancreas. These will be treated of in detail in the various animals composing the class Mammalia, and if time should permit, a review of the principal variations of the same parts in the other Vertebrata will follow. The lectures will be illustrated as fully as possible by specimens from the Museum, and by diagrams, and it should be added, are open without fee to any gentleman presenting his card at the door.

THE *Times* of India calls attention to the very scant recognition which literary or scientific merit has received in conferring the distinction of the Star of India. Although the Order of the Star of India was established for the reward of good service of every kind, and the soldier, the civilian, the diplomatist were not considered, on the institution of the Order, to have any better claim to the decoration than the man of science or the man of letters, yet on the list there is at the present time scarcely a single representative of literature, science, or art. The *Times* strongly commends the claims of Dr. Forbes Watson and Dr. George Smith to this distinction, for the admirable work done in bringing the English public face to face with the arts and manu-

factures of the East, services which have as yet received no recognition whatever from the Crown.

THE brilliant display of the aurora borealis, seen in London on Sunday night, of which various accounts will be found in our columns, appears to have been observed in France, as well as in Wales, Scotland, and Ireland. The phenomenon was seen in Turkey and also in Egypt. A telegram from Alexandria says that a large space of sky was illuminated for five hours. The report of the Meteorological Department on Monday notices the wide extent of the display, and adds, "a considerable change in the weather seems likely."

AT his inauguration as Rector of the University of Edinburgh on Monday last, Sir Wm. Stirling-Maxwell is reported to have made the following pertinent observations on the medical education of women:—"He was in favour of teaching women everything that they desired to learn, and for opening to them the doors of the highest oral instruction as wide as the doors of book-learning. As to medical education, he said that so long as women would minister to their sick children and husbands, he must hear some argument more convincing than he had yet heard why they were to be debarred from learning the scientific grounds of the art of which they were so often the empirical practitioners, or the docile and intelligent instruments."

THE *Academy* for February 1 contains a reply, by Prof. Helmholtz, to Prof. Jevons's article on "The Axioms of Geometry," in our issue for October 19.

WE learn from the *British Medical Journal* that the Brown Institution for Sick Animals is likely to commence at once a work of great public utility. Aided by a handsome grant from the Chambers of Agriculture, Profs. Sanderson and Klein, and Mr. Duguid, will undertake an extended series of observations on the treatment and comparative pathology of pleuro-pneumonia, an epizootic which commits the most costly ravages among our herds.

"JUSTICES' Justice" has become a proverb. Here is a sample of justices' science:—"At Chelmsford the county magistrates declined to grant the use of the Shire-hall for a lecture on the sun, illustrated by experiments in spectrum analysis, on the ground that the electric light might endanger the safety of the building!"

THE *American Naturalist* for January reprints a correspondence between the Commissioner of Agriculture for the United States' Government, and Prof. Asa Gray, and other botanists, respecting the dismissal of Dr. C. C. Parry from his office of botanist to the department, which appears to have been performed in a very summary manner, and on slight grounds.

MR. M. C. COOKE, the well-known mycologist, announces his intention, if the names of a sufficient number of subscribers can be obtained, to issue monthly a small journal, with illustrations, devoted absolutely to Cryptogamic Botany. It will serve as a sort of Appendix to the *Lichen and Fungi Floras* recently published, by recording and describing new species as they are found. Although British Cryptogamia will occupy the first place, it is intended to record from time to time what is doing abroad in all the Cryptogamic families (except ferns), and to keep the student acquainted with what is being published in foreign countries as well as his own. Monographs of genera and families, critical observations on species, and all kindred subjects, will receive attention. The co-operation is promised of the Rev. W. A. Leighton, Dr. Lauder Lindsay, Dr. Braithwaite, F. Kitton, and other specialists.

THE *Journal of Botany* states that a re-issue is in course of preparation of Lindley and Hutton's "Fossil Flora of Great Britain," originally published in 1837, and now very scarce. A supplementary volume will be added by Mr. Carruthers, which

will contain a critical revision of the species in the original book, and figures and descriptions of all the important additions to fossil botany made during the last thirty-five years.

A CLEVER application of science to commercial purposes has been made by an Italian gentleman, M. Eugenio de Zuccato, of Padua. By means of the invention any number of copies of a manuscript or design, traced upon a varnished metal plate, may be produced in an ordinary copying press. The *modus operandi* is very simple. To the bed and upper plate of a press are attached wires leading from a small battery, so that when the top of the instrument is screwed down the two metal surfaces come into contact, and an electric current passes. An iron plate resting upon the bed of the press is coated with varnish, and upon this surface is written with a steel point any communication it is desired to copy. The letters having thus been formed in bare metal, a few sheets of copying paper are impregnated with an acid solution of prussiate of potash, and placed upon the scratched plate, which is then subjected to pressure in the copying press. An electric current passes wherever the metal has been left bare (where the writing is therefore), and the prussiate solution acting upon the iron, there is found prussiate of iron, or Prussian blue characters, corresponding to those scratched upon the plate. The number of copies that may be produced by this electro-chemical action is almost unlimited, and the formation of the Prussian blue lines is, of course, instantaneous. The patent, which is, we believe, the property of Messrs. Waterlow and Sons, forms a remarkable instance of science serving as handmaiden to the man of business.

It will be remembered that a process of engraving by means of a forcible jet of sand was recently invented in America by Mr. Tilghman, and applied to photography, a gelatine relief being used as the mask or shield containing the design. The *Photographic News* states that a further modification has been patented by Mr. Morse, who uses a new method of propelling the sand. He provides a simple box or hopper, from which depends a small tube about 8ft. long, and no machinery whatever beyond this is used. A mixture of corundum and emery, in the form of powder, is placed in the hopper and allowed to descend through the tube. The object to be engraved is held under the extremity of the tube, so that the engraving powder will fall upon it, and in a few minutes' time the most splendid ornamental designs are cut, with marvellous exactitude and surprising beauty. An American paper says:—"We have seen engraved effects, produced by this process, upon glass and silver ware, that altogether surpass anything that has ever been attempted by the most skilled hand labour. This simple and beautiful invention promises to revolutionise the art of plate and glass engraving. By its use the adornment of all kinds of wares, in the most superb manner, may be quickly accomplished, at a tithe of the cost of the ordinary methods."

A CATALOGUE is printed of the Meteoric Collection of Mr. Charles Upham Shepard deposited in the Wood's Building of Amherst College, Mass., U.S.A. It comprises 146 litholites or meteoric stones, which are considered unquestionably authentic, from all parts of the world, the time of fall varying from the year 1492 to 1871, and 93 siderites or meteoric irons, which fell between 1735 and 1870. The total weight of the collection is above twelve hundred pounds. The heaviest iron, that of Aeriotopos, weighs 438 pounds; the smallest, that of Otsego, half an ounce. The largest entire stone, that of New Concord, weighs 52 pounds; the smallest, from Hesse, less than 50 grains. The whole number of specimens exceeds five hundred. The collection embraces, besides numerous casts, an extensive series of doubtful meteorites, in which all the principal irons and stones of this description are represented.

SCIENTIFIC INTELLIGENCE FROM AMERICA *

THE statement, by Professor J. D. Whitney, of the present condition of the geological survey of California, lately presented to the Governor of the State, gives a gratifying picture of the activity and success in accomplishing the objects for which the exploration was authorised. The State Geologist remarks that less has been done than he had hoped, in consequence of the suspension of the appropriations by a preceding Legislature. Since the work was resumed, however, as the result of renewed appropriations by the Legislature of 1869, the survey has been carried on as rapidly as the nature of the service would allow. Among the points particularly engaging the attention of the State Geologist was the completion of the topographical map of California, it being readily understood that this must be a necessary preliminary to a geological map. The survey of Central California was considered especially interesting and important, embracing, as it does, that portion of the State from Owen's Lake on the south to Lassen's Peak on the north, or between 36° and $40^{\circ} 30'$ north and south, and $117^{\circ} 30'$ and 123° east and west, the whole area comprising about one-third of the State, with probably ninety-five per cent. of the population residing in it. Of the portion included within these limits, represented upon four maps, three are entirely drawn and partially engraved, while the fourth is two-thirds drawn, with the field-work of the remaining third yet to be done. A preliminary map, however, of the whole of California, on a scale of eighteen miles to an inch, has been drawn, in compliance with the wish of the community, and will soon be ready for distribution. Besides these, other works connected with the same subject are reported by the State Geologist, being the new editions of the Yosemite Guide-book, and the publication of the first volume of the "Ornithology of California," which is characterised as a work exquisitely illustrated and admirably printed. The remaining volumes of the series of reports are so far completed as only to wait the continuance of appropriations to place them in hand and secure their early appearance. Arrangements have also been made with Mr. Lesquereux to work up the fossil plants of California, and with Dr. Leidy and Prof. Meek in regard to the fossils. Prof. Brewer, of the Survey, is well advanced in the work on the Botany of California, which, when completed, will doubtless be used extensively as a text-book. It is much to be hoped that very liberal appropriations will be made for these important objects, since its chief and his assistants are known to be among the very best specialists in America, and their work has commanded the highest respect among naturalists at home and abroad. The reports themselves are models of perfection in regard to typography and general execution, and are not to be surpassed by the finest European works, whether published by governments or private parties. It may be stated as a well-known fact that much interest has been excited throughout the scientific circles of Europe by the character of the work done under the auspices of the State, and the utmost admiration expressed in regard to its liberality and enterprise; this example being commended to European governments as eminently worthy of their imitation.—A letter from Captain Buddington, the sailing-master of Captain Hall's vessel, the *Polaris*, dated at Upernivik, reports that the party were in good health and spirits; and that Mr. Chester, the first mate, had gone up the coast to bring down Hans Christian, Dr. Kane's Esquimaux hunter, who was to join the expedition.—Among the many works published by the United States government, or at its expense, there are few that exceed in intrinsic value, as well as in beauty, the volumes hitherto printed belonging to the series of reports made by Mr. Clarence King, at his geological and other explorations of the region along the fortieth parallel of latitude. This expedition is still occupied in carrying out the work assigned to it by the engineer department of the army, while reports are now being made of such portions of the work as have been completed. It is nearly a year since the volume upon the mining industry of the Sierra Nevada and other mineral regions of the West was published, as prepared mainly by Mr. J. D. Hague (one of Mr. King's assistants), but including articles by Mr. King himself, and other members of the corps. This was accompanied by a large atlas of plates, and contained full details of all the methods of metallurgical operations and manipulations, together with drawings of machinery, plans of mines, sketches of mining geology, &c. This book has been received with great favour everywhere, and

has redounded greatly to the credit of the United States, first in authorising the research, and then in publishing the results in so superior a style. We now have to chronicle the appearance of another volume of the series—namely, the Botany, as prepared under the direction of Mr. Sereno Watson, the botanist of the expedition. This constitutes volume five of Mr. King's reports, and number eighteen of the professional papers of the engineer department of the army. The work embraces a report upon the geography, meteorology, and physics of the region explored as connected with the general botany of the country, catalogues of the known plants investigated, descriptions of new genera and species, and various appendices; these accompanied by forty plates of new or rare species. Another volume of the series is now in press, and will include the zoological portion, as furnished by Mr. Robert Ridgway. This will probably appear in the course of a few months.—The scientific tendency of the age, manifested in the continual springing up of new associations in different parts of the country, receives an additional illustration in the establishment of the Natural History Society of Marquette, Michigan, which was organised during the month of December, under the presidency of Dr. Hewitt.

ON THE CARPAL AND TARSAL BONES OF BIRDS *

THE author stated that he had followed with great interest the work of Huxley, Cope, Morse, and others, in tracing out the ornithic characters in the Dinosauria. While following these relations he had noticed a marked difference in the characters of the carpus and tarsus of the two classes. It seemed strange that a group of bones so persistent in the reptiles as well as in the mammalia should be so obscure or wanting in birds. Owen objects to the term tarso-metatarsus, as he believes the existence of a tarsus has not been demonstrated. W. K. Parker, in 1861, on the osteology of *Balaniceps*, questions if the lower articular portion of the tibia is not the homologue of the mammalian astragalus and not an epiphysis. Gegenbaur has now shown that in one stage of the young bird there is a proximal tarsal ossicle, and a distal tarsal ossicle, the first one anchylosing with the tibia, the distal one likewise anchylosing with the metatarsus. Thus, the term tarso-metatarsus is quite proper. While this was a great step toward a proper understanding of these parts, Mr. Morse believed that a nearer relation would be found in the discovery of another proximal tarsal bone. In those reptiles he had examined, whatever the number of tarsal bones, there were always in the proximal series one corresponding to the tibia, and another corresponding to the fibula. He had found this feature in birds. In studying the embryos of the eave swallow, bank swallow, king bird, sand piper, blackbird, cow blackbird, bluebird, chirping sparrow, yellow warbler, and Wilson's thrush, he had found three distinct tarsal bones, two in the proximal series answering to the tibia and fibula, and one in the distal series. The first two early anchylose, and present an hour-glass-shaped articular surface as Prof. Cope has described in the astragalus of *Laelaps*. The final anchylosis of these conjoined ossicles with the tibia, formed the bicondylar trochlea so peculiar to the distal end of a bird's tibia. The distal tarsal ossicle became united with the proximal ends of the metatarsus, as has been shown. In the carpus he had found four perfectly distinct ossicles, the distal carpal bones becoming united to the base of the mid and outer metacarpals, the other two remaining free, though the ulnar carpal in some cases anchylosed with the ulna. In the king bird and yellow warbler, he had found a fifth carpal on the radial side.

SCIENTIFIC SERIALS

THE *Journal of Anatomy and Physiology*, Second series. No. ix., November 1871.—The first article in this number is by Prof. Humphry, "On the Anatomy of the Muscles and Nerves of *Cryptobranchus Japonicus*," an animal which has been only rarely dissected. The muscular system presents no points of great peculiarity or interest, resembling very closely that of other *Urodela*. With respect to the nerves, no trace of the third, fourth, or sixth cranial could be found in either orbit, though the third and fourth, both of very small size, were found in the cranial cavity; previous dissectors had described the sixth as a

* Abstract of paper by Prof. E. S. Morse, read at the Indianapolis meeting of the American Association for the Advancement of Science. Reprinted from the *American Naturalist*.

* Communicated by the Scientific Editor of *Harper's Weekly*.

branch from the fifth in the orbit, but this could not be found in the present specimen. The three divisions of the fifth cranial nerve were distinct, but the ophthalmic and supra maxillary left the skull by a common foramen. The vagus gave off branches answering to the spinal accessory, and also a large lateral nerve which ran back along the body, giving off no branches until it reached the great lateral muscles of the tail, and in that differing from the corresponding nerve of fishes. The spinal nerves resembled in most points those of man very closely, the brachial and crural plexuses were, however, much more simple, which Prof. Humphry thinks is associated with a less perfect specialisation of the action of the limb muscles; and below knee and elbow the course of the nerve trunks in the fore and hind limbs was almost identical. The next paper is by Prof. Flower, "On the composition of the Carpus of the Dog." The os centrale had previously never been recognised in Carnivora, and both Cuvier and Owen regarded it as, in those animals in which it is present, as a dismemberment of some element of the carpus; Gegenbaur, however, regarded it as itself a true carpal element, though never able to discover the state of things in those cases in which it was absent. However, in the skeleton of a dog six weeks old, Prof. Flower finds that the so-called scapholunar bone consists of three distinct pieces, viz., a distinct scaphoid and lunar, and a third piece evidently answering to the os centrale; thus confirming the view that the latter is a true primitive carpal element.—Dr. Messenger Bradley gives an account of the brain of an idiot, who during life could taste and hear well, and could repeat a few words in a parrot-like manner, but was congenitally blind, and never recognised any one, or, although not paralysed, made any attempt at locomotion. His bones were extremely fragile, fracturing invariably if he jerked a limb against the bed. The brain when removed weighed twenty-eight ounces: most of the fissures and lobes of the cerebrum were present, but (notwithstanding the small size of the hemisphere) were relatively small. The island of Reil was small and very simple. The corpora quadrigemina were very small, which is interesting, taken in connection with his blindness. The cerebellum was relatively large, the vermiform process was imperfect, the pyramidal short commissure entirely absent, and the left hemisphere considerably lighter than the right. The bones throughout the body when examined microscopically were found permeated with oil drops and granular matter, but when these were washed away normal bone structure could be made out, except an unusually large size of the Haversian canals.—Prof. Young contributes some facts in the anatomy of the shoulder girdle of birds, showing that the only movement of the humerus in flight which is anatomically possible, is that in a figure of eight.—A short description by Mr. Watson, of the digestive, circulatory, and respiratory organs of the Indian elephant, follows.—The action of the chlorides of platinum, iridium, and palladium when introduced into the blood of dogs is the subject of an interesting paper by Dr. Blake, of San Francisco.—Prof. Turner describes the variations of nerves in the human body which he has lately met with, and then follows a paper by Prof. Struthers on the Great Fin Whale, the most interesting points being a careful account of the muscles of the fore-limb, helping to clear up some points as to the homologies of the bones; and the discovery, for the first time in this species, of a bony rudiment of the femur, though Prof. Flower had previously noticed a cartilaginous one.—Mr. Garrod gives some observations made on himself showing that the exposure of the nude body to a temperature below 70° F. causes a rise in the internal temperature of the body; which is greater the lower the temperature of the surrounding air down to 45°, the lowest point at which observations have been made. This he attributes to a contraction of the cutaneous vessels driving the blood inward, and also lessening the conducting power of the skin. Exposure to a temperature of 70° causes no rise.—A detailed description of the anatomy of the Malayan Tapir, by Dr. Murie, and of the muscles and nerves of the chimpanzee and anubis, by Mr. Champneys, do not admit of a short abstract being given of either of them.—The Report of the Progress of Physiology, by Drs. Brunton and Ferrier, is very full, and contains short accounts of many matters of great interest. The anatomy report is postponed.

SOCIETIES AND ACADEMIES LONDON

Geological Society, January 24.—Mr. Joseph Prestwich, F.R.S., president, in the chair.—The following communications

were read:—(1) "On the Foraminifera of the Family Rotalina (Carpenter) found in the Cretaceous Formations, with Notes on their Tertiary and Recent Representatives," by Prof. T. Rupert Jones, and Mr. W. K. Parker, F.R.S. The authors enumerated the Rotalina which have been found in the Cretaceous rocks of Europe, and showed by tabular synopses the range of the species and notable varieties in the different formations of the Cretaceous system. For the comparison of the Tertiary Rotalina with those of the Cretaceous period the following Tertiary formations were selected:—the Kessenberg beds in the Northern Alps, the Paris Tertiaries, the London Clay, the Tertiary beds of the Vienna Basin, and the English and Antwerp Crags. The authors also enumerated the recent Foraminifera of the Atlantic Ocean. The authors stated that of *Planorbulina* several species and important varieties of the compact, conical form occur throughout the Cretaceous series, and that those of the Nautiloid group are still more abundant. The plano-convex forms are represented throughout the series by *P. (Truncatolina) lobatula*; but the flat concentric growths had not yet come in. *Planorbulina* extends down to the Lias and Trias. *Pulvinulina repanda* is feebly represented in the uppermost Chalk, but forms of the "*Monardi*" group abound throughout the series. Species of the "*elegans*" group are peculiarly characteristic of the Gault, and some of the "*Schreibersi*" group are scattered throughout. These two groups extend far back in the Secondary period. The typical *Rotalia Brevanti* is not a Cretaceous form, but the nearly allied *R. unilobata* is common. *Tinoporos* and *Patellina* occur at several stages; *Calcarina* only in the Upper Chalk. The above-mentioned types are for the most part still living, but the "*auricula*" group of *Pulvinulina* is wanting in the Cretaceous series, as also are *Spirillina* and *Cymbalopora*, except that the latter occurs in the Maestricht Chalk. *Discorbina* and *Calcarina* make their first appearance in the uppermost Chalk. The chief distinction between the Cretaceous and the existing Rotalina was said to consist in the progressively increasing number of modifications. The authors concluded by disputing the propriety of regarding the Atlantic ones as homologous with the Chalk. The president suggested the possibility of some of the minute Foraminifera being transported fossils derived from earlier beds than those in which they are now found. Dr. Carpenter observed that the mode of examination to be adopted with Foraminifera was different in character from that which was applicable to higher organisms. The range in variation was so great that an imperfect examination of Nummulites had sufficed to make M. d'Archiac reduce the number of species by one half; and all the speaker's subsequent studies had impressed upon him the variety in form and in sculpturing of surface on individuals of the same species. When out of some thousands of specimens of *Operculina*, say, a dozen pronounced forms had been selected, such as by themselves seemed well marked and distinct, it might turn out that after all there was but one species present with intermediate varieties connecting all these different forms. He thought the same held good with Rotalina, and that there were oscular forms which might connect, not only the species, but even the genera into which they had been subdivided. This fact had an important bearing on their genetic succession, especially as it appeared that some of the best-marked types were due to the conditions under which they lived. The temperature in tropical seas differed in accordance with the depth so much, that when 2,000 fathoms were reached a degree of cold was attained such as was to be found in high latitudes; and in consequence the deep-sea forms in tropical latitudes assumed the dwarfed character of those in shallower seas and nearer the pole. He suggested caution in drawing inferences from forms so subject to modification, both spontaneous and due to the depth of the sea, especially as connected with abundance of food. Prof. Ramsay remarked that geologists would be pleased to find Foraminifera exhibiting, like other organisms, changes in some degree connected with the lapse of time. These low forms, however, could hardly afford criteria for judging of the age of geological formations, while at the same time such ample means were afforded by the higher organisms for coming to a conclusion. He cited, for instance, the Cephalopoda, as proving how different were the more important forms of marine life in Cretaceous times from those of the present day. He thought that no one who had thoroughly studied the forms of ancient life would be led to ignore the differences they presented, as a whole, from those now existing.—Prof. Jones, in reply, observed that the question of whether the Foraminifera in a given bed were derived or not was to be solved partly by their condition and partly by their relative proportions, but that in most

cases sufficient data existed on which to found a judgment. He agreed with Dr. Carpenter as to the existence of extreme modifications, and it had been his object to ignore such as seem due to ordinary and local causes, and to group the forms in accordance with certain characteristics. Whether the classification was right or wrong, it was necessary, for the sake of increasing knowledge, that fossils of this kind should be arranged in groups; and whether these were to be regarded as truly generic was a minor consideration. In forming their types and subtypes the authors had carefully avoided minor differences; but they still thought that the modifications which were capable of being substantiated were significant of a great lapse of time. A variation once established never returned completely to the original type. In *Gloßigerina*, he stated that there were in Cretaceous times 8 forms, in Tertiary 12, at the present time 14; and these modifications he regarded as equivalent to the specific changes in higher animals.—(2.) "On the Infraalias in Yorkshire," by the Rev. J. F. Blake. The Infraalias, *i.e.*, the zones of *Ammonites planorbis* and *Am. angulatus*, have been recorded hitherto only from Redcar, to the beds at which place the author referred; but the chief object of the paper was to describe some sections at Cliff, near Market Weighton, where these and lower beds were well exposed, and have yielded a numerous suite of fossils. He considered, however, that these beds did not belong to the typical Yorkshire area, but were the thin end of the series which stretches across England. He supposed there had been a barrier in Carboniferous times, which had separated the coal-fields of Yorkshire and Durham, prevented the continuity of the Permian beds, and curved round the secondary rocks to the north of it, to form the real Yorkshire basin, while these beds at Cliff were immediately to the south of it. The sections described were six in number, the first pit yielding the great majority of the fossils, and the third showing best the succession of the beds. The fossils could be mostly identified with known forms, and showed a striking similarity to the Hettangian fauna. In all the clays of the Infraalias Foraminifera were numerous and varied. The section in pit No. 3 showed, commencing at the top:—1. Stone bed with *Am. angulatus* (the fossiliferous bed of pit No. 1). 2. Thick clays, with bands of stone characterised by *Am. Johnstoni*. 3. One band of clay with *Am. planorbis*. 4. Thin-bedded stones and clays, some of them oyster-bands. 5. Clays without Foraminifera, and with impressions of *Astarte* (White Lias). The *Avicula contorta* series is not reached, nor are there any signs of the bone-bed, as the junction with the Keuper marls, which are found three miles off, is not seen. The paper was followed by references to the fossils mentioned, including the description of those that are considered new. Prof. Duncan remarked that English geologists had been backward in receiving the term Infraalias, which he had suggested with respect to the Sutton Down beds some years ago, and the propriety of which was shown by the term having been applied to the same beds by French geologists at a still earlier period. As to the White Lias, he regarded it as a mere local deposit, not to be found out of England. He traced the existence of the Infraalias from Luxembourg through France into South Wales, where corals were abundant. In Yorkshire, though one fine coral had been found, the Ammonites seemed to point to a difference in condition. Mr. Hughes remarked that the lithological character of the beds, as described by the author, did not agree with that of the Infraalias in the S.W. of England or the N. of Italy, and that the palaeontological evidence which had been laid before the Society did not confirm the view that they were Infraalias, the author having especially noticed the absence of *Avicula contorta* where he expected that it should occur. Also, by reference to the author's section, Mr. Hughes pointed out that below what he described as Infraalias he drew other beds which were not Trias, the author having explained that some beds which had been called Trias were only stained beds of Liassic age.—The Rev. J. F. Blake, in reply, acknowledged the difference between the Yorkshire section and those of the neighbourhood of Bath, but insisted on the similarity of the fossils.

Linnean Society, February 1.—Dr. J. D. Hooker, F.R.S., vice-president, in the chair. "On the Classification and Distribution of Composite," by G. Benham, F.R.S., president. The order Composite, or Syanthære, is remarkable, not only from its enormous size, but from its extremely natural and well-marked characters, there being not a single instance in which it is doubtful whether a plant should be referred to this order or not. All the essential characters of the androecium, pistil,

structure of the fruit, structure of the seed, and inflorescence are absolutely constant throughout the 10,000 species comprised within it. This very fact, however, renders its sub-division into tribes and genera a matter of extreme difficulty, the systematist being compelled to adopt characters as generic, which, in other orders, would hardly be considered as even specific. After briefly reviewing the labours of Linnaeus, Jussieu, Cassini, Don, Lessing, Schultz Bipontinus, De Candolle, Asa Gray, Hildebrand, Delpino, and other botanists who have paid special attention to this subject, the author spoke of the special opportunities he had had in the preparation of the "Genera Plantarum," in conjunction with Dr. Hooker, for examining himself nearly the whole of the genera comprised within the limits of the order, and then proceeded to the consideration of the value of the several characters available for the distinction of genera and tribes: 1. Sexual differences in the florets contained in the capitulum, which may either have both the male and the female organs perfect, or the female organs sterile in the central florets, or the male organs or both sets abortive or wanting in the marginal florets. These distinctions formed the basis of Linnaeus's order, but have been considered of less and less importance by subsequent writers. The author finds them sometimes constant in large genera or subtribes, sometimes variable in closely-allied species. 2. Di- and tri-morphism, very rare in Composite, except as connected with sexual differences. 3. Differences in the pistil. The ovary and ovule are uniform throughout the order, and the style nearly so when it acts only as the female organ; but the modifications of its extremity, in so far as they are destined to sweep the pollen out of the anther tube, supply some of the most important differential characters for genera, and even for tribes. These characters, first brought forward by Cassini, formed the basis of Lessing's and De Candolle's classifications, but have in many instances been too implicitly relied upon. 4. Differences in the fruit and its pappus. The structure of the fruit and seed is uniform in the order, but the outer shape of the achene and its ribs, angles, or wings have been made much use of, especially by Schultz Bipontinus, and the pappus presents such infinite variations so easily observed that it has been applied to the distinction of innumerable genera often very artificial. 5. Differences in the androecium. The male organs are as uniform in their structure, number, insertion, and relative position as other essential parts of the flower, but appendages often observed at the base of the anthers, usually called tails, having no apparent function to perform, are, however, so constant in their presence or absence, as to supply most valuable tribal characters. 6. Differences in the corolla, which, though uniform as to essential points in its structure and position, shows modifications of the limbo or lamina, which are of great importance as distinctive characters: (1) the pentamerous ligula of Cichoraceæ truncate at the end with five short equal teeth; (2) the regular tubular corolla, either slender and equal to the end, or expanded upwards into an equally toothed or lobed limb; (3) the bilabiate corolla, in which the two inner lobes forming the inner lip are usually shorter or smaller or more deeply divided than the three outer; and (4) the trimerous ligulate corolla forming the ray of most heterogeneous capitula, in which the two inner lobes are deficient or rarely represented by minute slender teeth. 7. Differences in the calyx. This organ is so reduced as to supply no characters except such as are derived from the ribs and pappus of the ripe fruit, and are considered under that head. 8. Differences in the ultimate inflorescence and bracts, *i.e.*, in the capitulum, its involucre, receptacle, and pappus, the modifications of which acquire a great degree of constancy and consequent importance in the distinction of genera or even of tribes, as might be expected from the increased functions imposed upon them by the abortion of the calyx. 9. Differences in foliage. There is no type of foliage in Composite which may not be found in several other orders, although the leaves are never compound with articulate leaflets, but the opposition or alternation of the leaves are of great assistance as characters of some of the tribes, differences in habit, stature, and general inflorescence, rarely giving absolute characters excepting where numerous capitula are crowded on a common receptacle into a kind of compound capitulum. 10. Differences in geographical distribution, which, if considered in so far as it may be attributed to origin independently of climatological considerations and modern colonisations, may be of great use in determining natural genera. In the portion of the paper now laid before the society and read in abstract the author enters into considerable detail with regard to the above several series of available characters, and concludes with a summary of the thirteen tribes which he has adopted for the "Genera Plantarum."

reserving for a future meeting the second part relating to the geographical distribution of the order.

Chemical Society, February 1.—Dr. Frankland, F.R.S., president, in the chair.—When the ordinary business of the Society had been transacted, a note "On the crystalline principle of Barbadoes aloes" was read by the author, Dr. W. A. Tilden, in which he described a new derivative of aloin. This is chloraloin, which crystallises from boiling-water in yellow silky needles, bearing considerable resemblance to the corresponding bromine compound bromaloin.—Dr. C. K. A. Wright then read an elaborate paper "On the relations between the atomic hypothesis and the condensed symbolic expression of chemical facts and changes known as dissected (structural) formulae," in the first part of which he showed the possibility of expressing chemical facts without reference to the atomic theory; and in the second examined how far these facts could be accounted for by the atomic hypothesis. A long and very interesting discussion ensued, in which some of the speakers advocated the employment of the atomic theory to a greater or less extent, as promoting the progress of chemical science, whilst others desired its abolition.

PARIS

Academy of Sciences, January 29.—A note by M. J. Boussinesq on the integration of the equation with partial derivatives of the isostatic cylinders produced in a homogeneous and ductile solid, was presented by M. de Saint-Venant.—M. A. Leduc read a note containing objections to the marine gyroscope proposed by M. E. Dubois at the meeting of January 22.—M. J. A. Serret presented a memoir on the pendulum of Léon Foucault.—M. Jamin presented a note by MM. A. Cornu and E. Mercadier on melodic musical intervals, confirmatory of their previous results.—A note by M. J. Violle on the induction currents produced in the polar masses of Foucault's apparatus was read.—M. Daubrée presented a note by M. Peslin on the bands of the solar spectrum, in which the author indicates a very simple relation between the most important bands.—M. Delaunay communicated a note by M. Fron on the prevision of certain earthquakes.—A further note by Father Secchi, on the temperature of the sun, was read, in which the author still maintains his opinion as to the enormous temperature of that body.—A note by M. E. Liais on absolute meridian observations in the low latitudes of the southern hemisphere was read, with special reference to the observatory of Rio de Janeiro. Upon this paper MM. Le Verrier and Laugier made some remarks.—M. S. Meunier communicated a paper on the methods which concur in demonstrating the stratigraphy of Meteorites.—M. Delaunay made some remarks upon the note presented to the last meeting of the Academy by M. Renou with regard to the Meteorological Manual of the Paris Observatory for 1872, and presented to the Academy the first number of a monthly Meteorological Bulletin published by the Observatory.—M. P. Thénard presented some observations upon the preservation of wines by heating, in connection with a recent note by M. Balard. He claimed the discovery of the action of heat upon wines for MM. Appert and de Verguet.—M. Chevreul read a note upon the investigations upon dyeing carried out by M. Paul Havrez; and M. Montégère-Levi and Kunzel presented a reply to a claim of priority made by MM. de Ruolz and Fontenay with respect to the discovery of phosphorus bronze and its employment in the manufacture of ordnance; M. Wurtz presented a note by M. L. C. Coppet on the supersaturation of the solution of chloride of sodium; and M. C. Bernard communicated a note on the analysis of the gases of the blood by MM. A. Estor and C. Saint-Pierre.—The lively discussion commenced two or three meetings ago on fermentation and heterogeny was reopened by a long paper on fermentations by M. E. Fremy, and continued by MM. Balard and Wurtz.—M. C. Martins read an important paper on the normal position of the hand in man and in the vertebrate series.

THURSDAY, FEBRUARY 15, 1872

THE POSITION OF THE CENTRE OF GRAVITY IN INSECTS

MY researches on the conditions of equilibrium in living beings, have led me to the conclusion that a complete knowledge of them is only possible when the position of the centre of gravity in each is known.

At present the knowledge of the mechanism of the Articulata has made considerable progress, thanks to the use of processes of investigation borrowed from Physics; and it appeared to me, that there would be real utility in the description of an easy method for the discovery of the centre of gravity in the Articulata, and the results which its application to insects has allowed me to obtain. I am, unfortunately, unable in a simple *résumé* to give a description of the instrument which I have employed. A very short description without an engraving is necessarily obscure, and loses all utility. I shall simply say that the instrument in question is a reproduction, on a small scale and with some improvements, of that which Barelli has invented for the determination of the centre of gravity in man. And with regard to the results of my experiments, I must also renounce the idea of giving them in the form they assumed in my work, that is, without the considerable number of figures combined in tables. I shall confine myself to the enunciation of the general conclusions I have been able to deduce, and to supporting them, as required, by several examples.

(1.) The centre of gravity in an insect is situated in the vertical and medial plane which passes along the longitudinal axis of the body.

(2.) It occupies a position almost identical in insects of the same species, the same sex, and in the same attitude.

(3.) The exterior form of the body rarely permits the determination of the exact position of the centre of gravity *without experiment*. I shall cite the results with which the family of Odonates have furnished me as examples. All its representatives have nearly the same exterior aspect; and yet, notwithstanding this *quasi* identity of structure, I have found in the relative position of the centre of gravity the following differences:—

<i>Agrion puella</i> , female	1st third of the 3rd abdominal ring.
„ <i>sanguinea</i> „	Posterior border of the 2nd abdominal ring.
<i>Libellula conspurcata</i> „	„ „ of metathorax.
<i>Libellula vulgata</i> „	Groove between thorax and abdomen.
<i>Æschna grandis</i> „	Middle of 2nd abdominal ring.

(4.) The centre of gravity does not occupy the same position in the two sexes of one species. It is sometimes less and sometimes more to the rear in the females than in the males; and its situation depends on the relations existing between the different dimensions of the individuals. One would suppose that the centre of gravity would always be situated further back in females than in males, as the abdomen of the former is in general more bulky than that of the males. During the metamorphosis from larva to perfect insect, the relative centre of gravity ap-

proaches the head; the absolute centre, on the contrary, recedes from it.* This apparent contradiction is very easily explained; the thorax of the larva is generally much reduced, and the abdominal rings numerous. In the perfect insect the thorax has acquired considerable dimensions, and the number of abdominal rings has diminished. The thorax, prolonging itself more to the rear, has approached, so to speak, the centre of gravity, which also remains in the medial region of the body; and the abdomen shortening itself, the distance of its extremity from the point in question diminishes.

(5.) While standing, the centre of gravity is placed at the base of the abdomen, or in the posterior portion of the thorax, and usually in the centre of the length of the body.

(6.) When an insect is walking, its centre of gravity undergoes constant displacement about a mean point, but the distances of displacement are too small to be measured. In fact, if experiments are made with leaping Orthoptera, grass-hoppers, or Acridians, it is ascertained that the displacement of their enormous posterior members leads to changes in the situation of the centre of gravity, but these changes are so small that one arrives at the conclusion that it is impossible to measure them in ordinary insects.

(7.) The displacement of the centre of gravity, when the insect passes from the state of repose to that of flight, cannot be ascertained except with those species where the wings lie folded on the back when in a state of repose. The displacement is horizontal and from back to front.

For example, in the following species the displacement is:—

<i>Dytiscus dimidiatus</i>	• 0.045	of the total length of the body.
<i>Hydrophilus piceus</i>	• 0.028	„ „
<i>Melolontha vulgaris</i>	• 0.053	„ „
<i>Notonecta glauca</i>	• 0.032	„ „
<i>Locusta viridissima</i>	• 0.054	„ „
<i>Vespa vulgaris</i>	• 0.023	„ „
<i>Plusia gamma</i>	• 0.025	„ „
<i>Eristalis tenax</i>	• 0.037	„ „

(8.) During active flight the centre of gravity oscillates continually about a mean position, which corresponds with the instants when the extremities of the wings pass the point of crossing of the 8-shaped curve which they describe in the air.

(9.) In aquatic insects the centre of gravity is nearer to the lower than to the upper surface of the body.

(10.) During swimming, the movements of the posterior feet, acting like oars, determine the oscillation of the centre of gravity around a mean position, which answers to the position of the swimming feet placed at the middle of their course. These oscillations of the centre of gravity lead to a continual swaying of the body about a transverse axis passing through the mean centre of gravity, and it ought, consequently, to follow a gently undulating course.

FELIX PLATEAU

* In my work I have called the relative position of the centre of gravity, its position as regards any portion of the body, as rings, hip *branches*, &c.; and I have named the absolute position of the centre of gravity the number which is obtained by calculating the relation between the distance of the centre of gravity from the posterior extremity of the body and the total length of the animal. The quotients, 0.50, 0.69, for example, obtained in this manner, mean that the distance of the centre of gravity from the posterior extremity is $\frac{1}{2}$ or $\frac{69}{100}$ of the total length of the body. They show immediately, and independently of the form and thickness of the rings, whether the centre of gravity is in the centre of the insect, nearer to the head, or nearer to the anal orifice.

ON THE COLOURING-MATTERS FOUND IN FUNGI

DURING the last autumn I studied very carefully the colouring-matters occurring in such fungi as I was able to find in my own district. For the correct specific determination of many of them I am much indebted to Mr. M. C. Cooke. Though the number examined was small, compared with the total number of British species, it was sufficient to lead to some interesting conclusions, and at the same time to point out the necessity of the examination of many more, which so far have not fallen under my notice. It therefore appears to me better to postpone the description of the individual colouring-matters until I can include a greater number, and compare them as a whole with those found in algae, lichens, and other natural orders; but at the same time it may be well to give a short general account of some of the conclusions to which I have been led by the facts already observed.

So far I have been able to determine, by means of their optical and other properties, the existence of at least thirty distinct colouring-matters, and I feel persuaded that further examination will greatly extend the list. The majority of fungi contain at least two, and many contain several, different coloured substances, which can be separated, or perfectly well distinguished by other means. Closely allied species sometimes contain two or more in common, but very often one or more differ; whilst, at the same time, species belonging to somewhat widely separated genera are occasionally coloured by identical substances—for example, *Stereum hirsutum* and *Peziza aurantia*. Notwithstanding this, on the whole, there does appear to be a very decided connection between the general organisation of the plant and the particular kind of colouring-matter developed in it. There is, however, a considerable variation, even in different individuals of the same species—one develops much of one substance, and another of another—and thus we can easily understand why we often find them of very different colours, with every intermediate tint. The connection between general organisation and the coloured products is still more decidedly proved by comparing those met with in fungi with those found in other natural orders. As already mentioned, I have been able to distinguish at least thirty different kinds in fungi. Of these fully twenty have such well-marked optical characters that they could be recognised without difficulty in other plants. Some of these could not be easily distinguished when mixed with any of the modifications of tannic acid, and therefore nothing very positive can be said about their presence or absence in certain plants. Confining our attention to those about which there is no such doubt, I may say that only one is known to occur in any plant not a fungus. This is the fine orange colour, soluble in bi-sulphide of carbon, found in *Calocera viscosa*, which agrees perfectly with the more orange-coloured xanthophyll of some faded leaves, and of the exterior layer of the root of the carrot. The rest have hitherto been found only in various fungi. Neglecting individual differences, and taking into consideration only such general characters as are most useful in dividing colouring-matters into natural groups, there is also a remarkable difference between those of fungi and of some

other natural orders. In several previous papers I have described how colouring-matters may be divided into three groups by the manner in which they are acted upon by sulphite of soda. In group A the detached absorption is removed, even when the solution contains free ammonia; in group B it is removed only when the solution contains excess of a weak acid, whilst group C is not changed in either case. So far, with only two exceptions, all the colouring-matters found in fungi belong to group C, even when they are blue or red, whereas with only two exceptions all the blue and red colouring-matters in the petals and leaves of flowering plants belong to groups A and B. A larger proportion of those of group C occurs in fruits, and a still larger in coloured woods, and thus the colouring-matters of fungi are much more closely related to those in woods than to those in flowers or leaves. As far as my observations extend, there is little or no specific agreement between the substances found in fungi and those in algae and lichens. These latter orders are, however, closely related in this respect, for the greater part of the specific colouring-matters found in algae occur in lichens, along with others similar to, but perhaps not identical with, those met with in fungi. Substances analogous to tannic acid are not of common occurrence, but are found in a few, as for example in *Agaricus sublateritius*, passing by oxidation into a very insoluble brown colouring-matter, as in the case of faded leaves in autumn.

I am most willing to admit that much still remains to be learned; but, at the same time, these various facts appear to prove that there is some definite relation between the organisation of plants and the chemical and optical characters of the compounds formed during their growth. If further research should establish this conclusion, one may perhaps indulge the hope that it will throw much light on certain questions in vegetable physiology.

H. C. SORBY.

SCHMIDT'S COMPARATIVE ANATOMY

Handbuch der Vergleichenden Anatomie. Eduard Oscar Schmidt. Sechste Auflage. (Jena, 1872.) Pp. 402.

IT is now more than twenty years since the first edition of this manual appeared. The plan is that of a companion to the author's lectures as Professor in the University of Gratz. It begins with a somewhat lengthy introduction on the general principles of Morphology and Physiology. In discussing the distinction between animals and plants, the author appositely quotes Buffon's dictum, "Il n'y a aucune différence absolument essentielle et générale entre les animaux et les végétaux." He also does full justice to the pre-eminent importance of Cuvier's labours in palæontology as well as in comparative anatomy and classification; but it is strange to find the name of Hunter conspicuous by its absence, even in a brief sketch of scientific biology. The lines which the author has chosen for the motto of his book,

Alle Gestalten sind ähnlich, und keine gleicht der andern,
Und so deutet der Chor auf ein geheimes Gesetz,

have, he believes, now received their solution. For Prof. Oscar Schmidt is a convert to the Darwinian creed. He says, "I have not freed myself from my old geological orthodoxy without much difficulty; and I am therefore

pleased to have finished this new edition, in which the breach is complete." The contents of the book show that this is no half-hearted conversion.

It is divided into chapters, each of which treats of the anatomy of one of the primary groups of the animal kingdom, and the following table of contents, not given in the work itself, sufficiently indicates the principles on which the arrangement is made. 1, Protista and Protozoa; 2, Cœlenterata; 3, Echinodermata; 4, Vermes; 5, Arthropoda; 6, Mollusca; 7, Tunicata; 8, Vertebrata. There is a good account of the Tunicata, or "Primeval Vertebrates" (Urwirbelthiere), from which the following is an extract.

After describing the characters of the ascidian larva as known before Kowalevsky's researches, the author continues:

"When the yelk-division has taken place, the ovum becomes first flat and then hollow on one side. A depression is thus formed, lined by two layers of cells (germinal laminae). From the more superficial of these are developed the skin and nervous system, from the deeper the notochord, muscles, and alimentary canal, the muscles arising in a secondary layer of cells derived from the deeper original one. A dorsal groove bounded by two longitudinal folds becomes rapidly converted into a tube, the spinal canal, and this is immediately followed by formation of the tadpole-like tail. . . . The primitive digestive tract is the depression described above, which first closes and then forms a new opening on to the surface, the future mouth. The branchial sack, alimentary canal, and cloaca keep pace with the other organs (those, namely, which are derived from the superficial or serous layer), and when the larva becomes fixed, the latter either disappears altogether, like the notochord, or undergo retrograde change, like the nervous system. Thus the original likeness of the larva to the vertebrate type becomes lost."

Each chapter begins with a pretty full survey of the classes, orders, and other sub-divisions in the group of which it treats, with their several characters. In looking through these, some points appear worthy of note. No mention is made of Gregarinida. Sponges are kept among the Protozoa. The account of this class is not so full as might have been expected from the author's familiarity with it; and with respect to its relation to the Cœlenterata, he merely remarks: "The early form of calcareous sponges, as well as the adult condition of certain genera, suggest a comparison with the Cœlenterate type." The Tunicata are removed from the worms, but Infusoria are added to this heterogeneous group, which, with Prof. Schmidt and most German naturalists, includes Bryozoa and Annulata, and probably contains as many distinct types as it did when Linnaeus first defined it. Among the Arthropoda, *Limulus* is placed between the Amphipoda and Branchiopoda, as the type of the Crustacean order Pœcilopoda, while the Myriopoda do not appear at all. The Pteropoda form an order of the Gasteropoda, or (as they are inconveniently called) Cephalophora. The Vertebrata are divided into seven classes, *Amphioxus* and the Cyclostomi being both separated from Pisces, and made into independent primary divisions. Dipnoi appear as the highest order of fishes, separated from the Ganoids by Teleostei. Among the monodelphous mammals it is surprising to see the Sirenia still united in the same order with the true Cetacea; while, on the other hand, the

Pinnipedia are separated from the other Carnivora. The order Primates is broken up by the exclusion of *Homo* altogether, and the separation of the Lemurs (Prosimia). The author agrees with Haeckel and Gegenbaur in regarding this last order as the lowest of the Discophorous Mammalia, and as representing the ancestors of that group.

The morphological description in each of the above chapters embraces in most cases too wide a subject for the space allotted to it. Even in Gegenbaur's work one finds the Vertebrata, and still more the Vermes, too extensive for the anatomy of the whole group to be conveniently considered at one view, and, not only is Schmidt's style less concise, but is not illustrated by diagrams of any sort. The account of the vertebrate skull and of the specialisation of the somites of Arthropoda are instances of the deficiency referred to. Moreover, there is generally much too cursory an account of Embryology in comparison with other subjects. Indeed the development of Vertebrata is entirely omitted. The bibliography is evidently intended as a guide for students to the latest and most accurate works in each department, and for that purpose is fairly complete and well selected; but there are some remarkable omissions, as of Mr. Parker's monograph on the shoulder girdle.

On the whole, this expanded syllabus is interesting, as a fresh instance of the progress which "the new zoology" is making abroad; but its chief practical value will probably be to those who have the advantage of hearing the author's lectures. For them the wish with which he sends out the present edition will no doubt be amply fulfilled: "I hope that it will remain what it has been, a book for students, and will keep me in that active intercourse with young minds which ensures to a university teacher the freshness of thought, the imagination and openness to new ideas, which he can so ill afford to lose."

P. H. PYE SMITH

OUR BOOK SHELF

Text-Books of Science. Technical Arithmetic and Mensuration. By Charles W. Merrifield, F.R.S. (Longmans and Co.)

ARITHMETIC is a science as well as an art, and although the title of this book points solely to the art of arithmetic, we are bound to examine how far it has supported its right to a place in the series of text-books of science. The author says in the preface that "his experience has led him to believe that there is not much practical connection between successful teaching and logical sequence. The province of logic is to test ideas, not to impart them." We venture to demur entirely to these propositions, and to assert that each successive idea acquired by the pupil should be made to follow logically from the ideas previously existing in the mind, and that ideas which cannot stand the test of logic are, in an educational point of view, worthless.

We proceed to select a few instances of the disregard of logical sequence which the author considers compatible with successful teaching. (1.) The only definition of division given is the following:—"The object of division is to find how many times one number is contained in another. This number of times is called the quotient." A few pages further on is given the method of dividing *l. s. d.* by 365, and no hint is given that a different interpretation of division is required, viz., distribution of the

money into so many parts, and not finding how many times the number 365 is contained in so much money, which is meaningless. (2.) Multiplication is said to be only a shorter method of "getting at" a particular kind of summation; but when we come to fractions we are told parenthetically that to multiply 7 pence by $\frac{3}{4}$ is to take three-quarters of it, without any discussion of the extension of the very meaning of the word multiplication that must be made before this interpretation is intelligible. In the same way we are told that one way of writing $289 \div 17$ is $\frac{289}{17}$ before the important truth has been impressed on the pupil that $\frac{1}{3}$ of 3 = $\frac{3}{3}$ of 1, so that a symbol is used in two distinct senses before the identity of those senses has been shown. Throughout the book all difficulties are slurred over with half reasons, which are to be accepted by the pupil as whole ones. There is no attempt to lead the pupil to discover the rules for himself, or to trace the way in which they were originally arrived at; while at every turn we meet with such expressions as "evidently," "it is clear," "it is easy to see," "there is no mystery about decimals," as substitutes for the considerations which should really connect the new rules with the previous knowledge of the pupil. We might pick out specimens of this want of thoroughness from almost every page, but we must now turn to the art of arithmetic. The author says "care has been taken not to introduce anything in the way of mathematical invention or discovery," but surely care should also have been taken that the book should not be behind those already published in the brevity and completeness of the methods given. The rule for contracted multiplication is given, but its application to complicated calculations, such as practice, interest, stocks, &c., is left untouched. Contracted division is mentioned, but is not applied to the only case where it is indispensable, division by an interminable decimal. Decimalisation of money is taught, but by the old clumsy method; while a mode of approximate decimalisation is given, which is of no use if the result required be greater than the given amount. The latter portion of the book is devoted to mensuration, in which considerations that belong to the higher mathematics are described as evident, while all mention of the mensuration of rectangles and the difference between linear, square, and cubic feet is omitted. The book is below the level of the more advanced thought of the age, and unworthy to take rank in the series which contains "Miller's Inorganic Chemistry," and "Maxwell's Theory of Heat."

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

The Total Eclipse as seen at Ootacamund

As a photographer and an ardent lover of science, I was of course anxious to catch an image or two of the eclipse, as a memorial of the grand scene of the morning of the 12th inst. Unfortunately for me, I read a short time ago an article by Mr. Brothers, of Manchester, on photographing eclipses, in which he says that it is useless to attempt a photograph of an eclipse without an equatorial stand to fix the camera to. Inquiries soon convinced me that in a primitive place like this it was impossible to get such a stand, and, in consequence, I gave up all idea of making an attempt at taking a photograph of the eclipse. The eclipse, however, no sooner commenced, than I laid aside my telescope and brought my camera into use to watch the progress of the eclipse, with the aid of a strong magnifying glass on the focusing screen of the camera. Here I saw that the progressive movement was scarcely perceptible; and that, with a short exposure of three seconds, I might get an image: though not perfectly sharp, yet it might show all details necessary for forming an interesting memorial of the eclipse.

I prepared one plate some time before totality, washed it, so

that it would keep good for an hour or so, and some time after totality had commenced I exposed it for three seconds, and developed it some time after totality. As far as I know I exposed the plate 75 seconds after the commencement of totality, and the result was the plate I had the pleasure to hand to you, and the prints you saw in my place were printed from it. I may add that the plate was taken with a No. 6 D. Dallmeyer's lens, with the full opening and without a stop.

I will digress for a moment and express my surprise that I hear that the photographers of the Expedition parties obtained only five or six plates during totality, and that they gave exposures of about 15 seconds. If I had exposed my plate 15 seconds instead of three, I should have had nothing remaining but "a foggy ghost." There must have been a great want of proper balance in their chemicals. Again, they seem to have been provided with a number of slides, or camera-backs, to hold a certain number of prepared plates. Now, had I known that I could obtain tolerable results without an equatorial stand, I would have presented you with a plate of at least eighteen different photos of totality. As my idea may be useful on a future occasion, I will shortly mention it. Photographers are in the habit of taking 2, 4, 6, or even eight cartes de visite photos on one single plate, and often also with one lens only, by an arrangement which we call repeating backs. A slight modification of the repeating back would have enabled me, or any one else, to take in quick succession, without loss of a second, at least 18 or 20 photos of the eclipse on one single plate. Different exposures might have been given to some or to all, and a treble number of photos to what has been obtained might have been secured without additional expense, and with less trouble. Any apparatus-maker would furnish such a slide for about 40s., and as the operator would have only to pay attention to one slide and one plate, he would work with more certainty and comfort. If any one will say that one good photo of the eclipse was all that was needed, I must say that I differ from him. I observed most distinctly that the shape of the corona was undergoing a regular dissolving view process, and had not for two seconds exactly the same shape. Of this more hereafter.

The eventful day commenced here in the centre of Ooty, with the sky overcast both in the east and west with dark grey clouds. The camp of the Expedition on Dadabetta appeared enveloped in fog, so that the early prospects of the members stationed there must have been rather gloomy. In the town where I was the eclipse was visible from the very first commencement to the last moment; only once, for a few seconds, during the earliest stage, a small cloud obscured the sun. The grey, gloomy clouds receded (as if inspired with fear) as the eclipse advanced, in the direction of all four points of the compass, and the atmosphere between the earth and the sun and moon appeared of that absolute pure and blue hue, which can seldom be seen anywhere else except in high mountains. The scene as seen from the centre of Ooty was a grand sight. Every eye was turned to the east, the curious play of colours around the hidden sun, the general gloom, or want of light, the ghostly shadows thrown by trees and other objects, the clear appearance of the stars in the west, combined with the solemn stillness (which we enjoyed at Ooty) not a breath, nor a leaf moving, combined with all the other novelties of a total eclipse, formed a scene which is easier imagined than described. Chickens and fowls were of opinion that the day was ended, and retreated to their roosts, and many old people (natives of course) hid themselves in their huts, filled with the anxious expectations of the things which were to come. The whole scene was still more enhanced by a large assembly of natives which had assembled near my place. Their exclamations of fear, of terror, and awe, were very amusing if not distracting. Now their fear showed itself by short and earnest incantations or prayers to a certain good deity to deliver the sun from the cruel fate of being swallowed by the large serpent, which, in their opinion, constantly pursues the sun, and overtakes it during an eclipse, and when only the interference of a good deity can save the sun from the fearful fate of having to undergo digestion in the belly of the terrible serpent. Some began to smite their breasts, and pluck their hair, accompanying these acts with exclamations which betrayed no small amount of mental agony about the probable fate of Father Sol; others watched in trembling silence, awaiting the end with fear, but which might yet be fulfilled. The prophecies of the holy Brahmin might yet be fulfilled. Higher and higher rose the excitement, until the entire sun was engulfed in the terrible serpent's mouth. But it happened, as the Brahmins had foretold, a powerful good deity cut off with one blow the big serpent's head, and the sun, instead of going

down the serpent's throat, emerged slowly in all his glory from the opposite side.

If science gains as much in knowledge by the observations made by the different eclipse parties as the wily Brahmins have gained by this late eclipse in money, then a great deal of knowledge will have been gained about all those mysterious phenomena by which Father Sol is still surrounded; for every village in India, as far as the country was affected by the eclipse, paid willing contributions to the Brahmins, that these holy men might use all their influence (by prayers, fastings, and offerings) with their deities in order to induce them to come to the rescue of the sun in the hour of his great danger and need; and I hear that the Brahmins hereabouts had an abundant harvest in money from the poor villagers, to whom they preached months before the great danger impending over the sun; and as these poor people are not yet bold enough to doubt a single word of these heaven-born Brahmins, they contributed to the best of their abilities to the Brahmins, in whose hands, as they believe, rests not only the fate of men but of the whole universe, as the Brahmins are the connecting links between men and the deities ruling this and other worlds. An event like the eclipse shows how much importance is to be attached to all the reports and writings about the great progress in enlightenment of the people of India. Knowledge does not reform their manners; many well-informed and educated natives performed all the superstitious ceremonies connected with the eclipse, with just as much zeal as the ignorant ryot, and many of those who talk to us Europeans about the folly of all the old superstitions, went back again, and performed their rites in the manner of their forefathers, fearing, that if they did not do so, Father Sol might be lost for good, and that we might have to end our remaining days in the constant gloom of starlight.

I have already mentioned that, as far as my observations go, I observed that the shape or form of the corona or glory which surrounded the eclipsed sun underwent changes in form even during the short space of two minutes; but you will easily see that an observer with no other means than an ordinary good telescope, his naked eye, and a photographic camera, was quite incompetent to draw any conclusion; suffice it therefore to say that the changes in the shape of the corona during totality can but be compared to the slow transformation of forms in a dissolving-view apparatus, or perhaps more correctly to the changes of form and shape we observe in isolated thin clouds. I will not express more of my opinion on the nature of the corona than that I believe it consists or partakes of the nature of shining, illuminated ether, perhaps somewhat of the same nature as the aurora borealis; why I think so will appear below.

About eight or ten seconds before totality ended, the moon appeared as if it had made a jerk (stumbled against something), and that jerk was accompanied by a tremendous flickering movement and momentary brightening up of the corona. This momentary phenomenon (for all passed in less or not more than one second) I am unable to describe more clearly, and I cannot compare it to anything except to those flickering movements and brightenings up observable in the aurora borealis. I spent one entire night during the winter of 1845 in watching a grand aurora borealis in North Germany, but had nearly forgotten all about it, but the above appearance in the corona towards the close of totality reminded me so forcibly of it that I hold that something similar is connected with the corona. I was watching the eclipse with a strong magnifier in the camera obscura, and three gentlemen near me used telescopes, and we all observed the same—I in the camera, and they with their telescopes—and the flickering caused us all to express some surprise, such as "Look! look!"

In the evening I had some conversation on the eclipse in general with the telegraph master, a very scientific gentleman, who, without my saying anything about the matter, told me that he observed such a phenomenon.

I think this is about all I can say, as the play and changes of colours which were visible are quite beyond my sphere; I can only say I saw them, but I do not remember their order and succession, nor changes.

In conclusion I must once more repeat that what I say must be taken for what it may be worth. I merely speak of the appearances without accounting, or being able to account, for them; and this will not be surprising when those who spend their lives in these studies can often only offer conjectures as to the real nature of these matters.

Ootacamund, Dec. 22, 1871

J. BOESINGER

Natural Science at Oxford

THE regulations relating to Natural Science at Oxford, reprinted in a recent number of *NATURE*,* will have considerable interest for those who follow the progress of such studies at the Universities.

The Natural Science Schools is one of the five "Final Schools." There are examinations which take place at the end of the University course; in any one or more of them it is open to candidates to seek for honours. Hitherto the Natural Science School has offered a threefold division of its subjects, namely, Biology, Physics, and Chemistry. A candidate was allowed to select any of these three divisions, and was expected to show, in the first place, a general acquaintance with the subject matter; and in the second, a detailed knowledge of some particular branch of it. The selection of the "special subject" was left entirely to the candidate, but the liberty of choice (in theory a most valuable one) was frequently altogether abused. The object was, apparently, in many cases, to turn the tables on the examiners, and by selecting matters likely to be out of the way of their reading, to make the examination almost fictitious. It is to remedy this that the new Board of Studies has laid down the scope of the general and special knowledge which will be required from candidates for the future.

The regulations at present published relate only to Biology. I venture to think that they by no means form such a philosophically-arranged course as might have been expected.

The first paragraph states the nature of the *general* knowledge which will be demanded. This is defined to consist of General and Comparative Anatomy, Human and Comparative Physiology and Physiological Chemistry, and the general philosophy of the subject. The books recommended are the best commentary on the meaning attached to these headings. The list certainly does not err from defect of copiousness, yet it is noticeable that although it contains all the common zoological text books, it does not include any distinctively botanical book whatever. I do not mean to say that some of the authors named in it do not touch on Botany, but this is so far accidental that they apparently owe their position on the list to their bearing on zoological matters. It appears to me therefore that the only conclusion which can be arrived at from the regulations is that by Biology is not intended General Biology, but only Biology from a zoological standpoint. This is, I think, to be regretted. A general acquaintance with the principal forms of vegetable life ought to form part of a comprehensive biological course, and should be required even of those who intend to devote their strength to the study of the animal economy alone.

The fifth paragraph appears to admit of Botany being taken up to a certain extent as an alternative subject, but this does not remedy its practical absence from the general scheme. I can see nothing in the regulations to preclude a candidate taking high honours in "Biology" who shall, for example, be quite ignorant of the anatomical differences between a cycad and a palm, or shall be quite unable to indicate any points of agreement between a mushroom and a mould. Any one in this predicament might perhaps excuse himself as a zoologist, but he can hardly be allowed to claim the whole of Biology as his province.

W. T. THISELTON DYER

Auroral Statistics

HAVING had already to answer many questions and calm some fears touching the recent brilliant aurora, and its prototype in October 1870, "when the Franco-German war was raging," I beg to send you some condensed statistical returns of auroral phenomena during the last eleven years, prepared and printed before the recent manifestation, and to be published in a few days, but as a part of a ponderous volume not likely to be generally accessible, viz., vol. xiii. of the "Edinburgh Astronomical Observations."

In that book I have endeavoured, amongst other subjects of professional duty, to exhibit the final mean results of nearly 7,025,000 meteorological observations of all kinds, by 55 observers of the Scottish Meteorological Society, spread over the country at as many stations; and, after a preliminary process of compression into 32 numerical tables, the quintessence of the whole appears on a single page, whereof the 28th line gives a numerical expression for each month of the year; combining the

* See *NATURE*, No. 118, p. 270.

number of times that aurora was visible with the extent of country over which it was observed, and the numbers stand thus:—

January	...	29.7
February	...	42.5
March	...	35.0
April	...	27.5
May	...	4.8
June	...	0.0
July	...	0.5
August	...	12.6
September	...	36.0
October	...	49.4
November	...	32.4
December	...	28.8

It will thus be seen that October and February are precisely the two months when brilliant auroras are most likely to be seen; and that of these two maxima of the annual cycle October has rather the advantage.

The lightning return, prepared on the same principle, is not uninteresting to be compared against the aurora; for, though both in its aerial altitude and actual numerical returns, lightning may be the very opposite of aurora, yet it exhibits a tendency to a similar double maximum in the course of the year; and not a few of the lightning storms of that second, or winter maximum, are locomotive "meteors," travelling from S.W. to N.E., and having undoubtedly a very wide-spread earth-influence and physical significance. The actual numbers are these:—

January	...	24.0
February	...	14.4
March	...	7.0
April	...	15.4
May	...	37.4
June	...	48.0
July	...	53.2
August	...	38.4
September	...	22.4
October	...	20.8
November	...	15.0
December	...	15.0

C. PIAZZI SMYTH

15, Royal Terrace, Edinburgh, Feb. 10

The Aurora of February 4

I WILL not attempt to describe the wonderfully gorgeous display of aurora which I witnessed on Sunday night, February 4. I merely wish to mention a circumstance connected with it which may have some interest. I was watching for the zodiacal light at about 5.30, and, having perceived faint traces of it, I presently saw some peculiar red clouds a little above it; from their rapid change of form I soon became aware that this was the light of an aurora. From that time, and from that spot, it spread rapidly; a bright white arch extending high overhead from W. to E., while a segment of blue sky stretched low down in the

S.E. in the magnetic meridian, the space between being filled with brilliant colours. Shortly after this a radiating point became very striking, not in the zenith, but at one-third the distance from the Pleiades to Capella; and then the folds of gorgeous light-red, white, and faint green, interspersed with dark shading, spread from it, like a canopy, down on all sides except in the N.W. I never witnessed or read of such a display in these latitudes. With one of Browning's small star spectroscopes the spectrum consisted of a small portion of brilliant red, then a bright band rather close to it, and then two others beyond; the two latter

being rather nearer together than the first and second; that at the more refrangible end being the faintest, and that near the red the strongest. I enclose a sketch showing the spectrum, the slit being wide open.

The maximum display was between 6.45 and 7 P.M.; at 7.15 it was fading rapidly. Clouds covered the sky at 7.30, and some smart electric showers fell; still I could see that the display was going on, and at 11 P.M., in spite of dense clouds, the light was sufficient to enable me to read large print.

HENRY COOPER KEY

Stretton Rectory, Hereford, Feb. 6

ON Sunday evening 4th inst., a beautiful display of aurora was observed here (lat. $51^{\circ} 26' 0''$ N., long. $0^{\circ} 20' 53''$ W.). My attention was first directed to it at 6h. 4m. (G.M.T.) at which time there was a fiery glow over a considerable portion of the southern sky, much resembling the reflection of a distant conflagration. Shortly after, an almost complete auroral arch, of faint orange red light, similar to that at first observed, was noticed, extending from E., above and partly embracing δ , ϵ , and ζ Orionis, to W., its altitude (by estimation) at the centre being about 40° , and its extent something like 120° . For a short time this glow was most intense in S.E. at a great altitude, but the display attained its greatest intensity about 6h. 15m., when a number of rays or streamers of whitish blue and orange red light appeared as if radiating from a point near δ , α , and κ Persei. At 6h. 20m. nothing was observed but a widely diffused fiery glow, which must have continued more or less during the whole evening, as it was again observed by me at 8h. 25m.

JOHN JAMES HALL

Fulwell, near Twickenham

THERE was a fine display of the above phenomenon here on Sunday night, February 4. At five o'clock a muddy undefined redness made its appearance in the N.E. and W., especially in the former, which continued for some time without any very marked change. Towards half-past six the redness became more concentrated, gradually brightened, and finally became of a most intense brilliancy—indeed, so much so that it fairly baffles description, the landscape and the countenances of those standing near being visibly tinged. Streamers soon began to form, and shoot gradually upwards from the horizon in all directions from N.E. by S. to W., some intensely red, some very white, while others were of a greenish hue. The red and white being very brilliant, were finely intermingled, especially in a N.E. direction, while a muddy green prevailed chiefly in the S., and a reddish tinge in the W. By seven o'clock that rare phenomenon, a corona, was formed overhead, assuming a variety of shapes. The most curious part of the display (as far as my experience goes) was the entire absence up to this time of any streamers or coloured haze in a W. by N. to N.E. direction, the sky being cloudless, perfectly clear, and the stars shining with their usual brightness. On the formation of the corona a sheet of fan-shaped sea-green haze shot from it in a N. direction, spreading rapidly as it advanced, but did not proceed for more than 20° , when it suddenly disappeared. The streamers were remarkably steady throughout, and straight, unlike those during the display of November 10 of last year, which were wave-like, rapid, and flickering. By half-past seven the entire sky had assumed a greenish tinge, with a reddish glow in some places, and a few resplendent beams of white light from the E. chiefly. At a quarter to eight red streamers became visible in a N. direction, at a considerable elevation, resting on a greenish haze, itself emanating from a very indistinctly white arch spread across the N. At nine the sky was still tinged, and a streamer here and there visible, but by ten the display was over, as clouds had obscured the heavens. Although the red colours were so intense and deep, the stars could be distinctly seen through them, and when the streamers suddenly changed to white, &c., it was possible to see the time on a watch, though the night under ordinary circumstances would have been dark. A common dipping needle which marked 56° at noon changed to 45° before the aurora became visible. Barometer corrected and reduced, 29.748. Temperature, 37° at the time. Solar radiator during the day, 77° . A few shooting stars darted across the heavens in a south from east direction, mainly during the aurora. A wet night afterwards set in.

THOMAS FAWCETT

Blencowe School, Cumberland, Feb. 5

A VIEW of the magnificent aurora of Feb. 4 was much interrupted here by great masses of cloud, which frequently drifted over large tracts of the illuminated sky, and towards 8 o'clock collected and descended in a general downpour of rain. Nevertheless enough of it was seen to produce a very striking impression. It began to tinge the southern sky at a considerable altitude so early in the evening that I thought it must have been the reflection of a crimson sunset; nor was I undeceived till I had been to the other side of the house, where I found the western horizon glowing with amber light, in which was no trace of the expected ruddiness. Red continued throughout to be the prevailing hue, chiefly in great diffused masses, but occasionally broken up into filaments and streamers; there was, however, no absence of sheets and columns of the more usual pale green light. The clouds, chiefly heavy cumuli, assumed a strange aspect; sometimes, when opposite to the crimson illumination, reflecting a dull and sombre red, at others, when projected in front of it and enlightened from the other side by the twilight, or the green aurora, standing out in lurid and ghastly contrast. At one period the northern part of the sky, up to a great altitude, though clear and studded with stars, appeared at first sight almost like a black cloud from its contrast to the greenish white sheet which bordered it abruptly at a considerable height on the west; this again passing into crimson masses in the south, and sending out a whitish stream to meet another from the east, and form, probably, for a few moments, a complete bright ring, somewhat south of the zenith, of which, however, only one half could be seen from the post of observation. The light was so intense that even after it had been a good deal obscured by cloud, a large print might have been read without much difficulty. A miniature spectroscope (one of Browning's) brought out some interesting features. The usual yellowish green auroral line was distinct everywhere, and could be perceived even when the instrument was directed to masses of dense cloud; and as was observed by Birmingham on a former occasion, could be made out in the reflection from any suitable terrestrial object; white paper for example exhibited it very obviously. As shown in the brighter greenish patches in the sky, it remained visible even when the slit was so much contracted that the sodium band of a common fire would have been thinned down almost to its smallest breadth before extinction. Such a diminution of light, however, was fatal to the rest of the spectrum, which was a very remarkable one. With a wider slit a crimson band, bearing a fair amount of contraction, was perceptible in the brighter patches of that hue, with a dark interval between it and the principal green band. On the opposite side of that green band, beyond a second similar dark space, was a considerable extent of greenish or bluish light, quite decided, but so feeble as to leave it undecided whether it was of uniform brightness, or (as I suspected) compounded of contiguous bands; beyond this again was another dark space, leading on to a faintly luminous band, too dim to show colour, but which must have taken its place somewhere in the blue. This band, and the darkness adjacent to it on the less refrangible side, were each about as broad as the intensely vivid yellowish green stripe. Could the light have borne sufficient reduction, we should certainly have had three narrow bright bands in the red, green, and blue, the two latter being wide apart, with either a faint separate continuous spectrum, through part of the interval, or possibly several feeble lines, which the widening of the slit fused into one lengthened arc.

The peculiarity, first noted I believe by Otto Struve, was very obvious, that even where the naked eye recognised the strongest and fullest crimson without a trace of green, the greenish yellow band in the spectroscope far exceeded, perhaps three or four times, the red line in visibility. This display was distinguished from almost all that I can recollect to have witnessed through many years, by its very feeble development in all the northern portion of the sky.

Hardwick Vicarage, Hay

T. W. WEBB

WILL you kindly permit me to correct an error which crept into my letter of last Monday on the aurora. The words "western" and "north-eastern" in the 14th line should have read respectively "eastern" and "north-western." Allow me also to call attention to the present condition of Jupiter. On Thursday evening last the equatorial ochre-tinted belt was lighter in colour than I have seen it of late years, but much and distinctly mottled with light and dark clouding, two dark hanging spots on the upper edge, with adjoining elliptical bright patches,

being conspicuous, while the lower dark madder-brown edge was very unequal, being swollen and thick about one-third to the right from the centre, and thinning off towards each end. The dark belt above the equatorial zone had two knots or thickenings of considerable size upon it, and the whole series of belts presented ragged and dentated edges, and, to use the apt phrase of a lady who saw them, had a "mountainous" look.

On occasional glimpses I more than suspected a general mottling of the whole surface of the planet, which, moreover, presented a dull appearance, the dark and light belts and spaces not being, as I thought, so well contrasted as usual. The poles were coloured as in ordinary, the upper one warm and ochreish, the lower slate grey. The instrument used was Browning's 81 reflector, full aperture, with inserting achromatic eye-piece 306. A transit of a satellite and its shadow added to the general effect.

Guildown, Guildford, Feb. 10

J. R. CAPRON

ON Sunday, the 4th of February, at 10 P.M., I observed the central point of the "corona" of the aurora visible that evening to be situated between 4, 64 and 65 Geminorum, in R.A. 7h. 20m. and N. decl. 28'. Our latitude is N. 50° 50' 55", and longitude E. 0° 32' 50".

The "corona" drifted away very slowly towards the E. against a slight E. wind blowing at the time.

Perhaps some of your contributors can calculate the aurora's height from the earth from the above notes, and let us know the result through your journal.

J. E. H. P.

St. Leonard's, Sussex, Feb. 12

NOT wishing to trouble you with a long description of the aurora observed by so many on the evening of the 4th, I will confine myself to a few remarks. The spectrum of the brighter portions, viewed through a five-prism direct instrument, consisted generally of the four lines mentioned by Captain Maclear; but when the spectroscope was turned towards the brightest of the curved streamers forming that splendid red and pink star, which so suddenly burst forth at 7:25, some degrees south of the zenith, the relative intensity of the lines was completely changed, the red line becoming more strongly marked even than the green.

The fact that the green line can always be detected, even where the unassisted eye fails to notice any trace of auroral light, might suggest the advisability of a daily observation with a small hand spectroscope for those who are desirous of forming a complete list of all auroral phenomena. Magnetic disturbances are a sure guide in the case of grand manifestations of aurora; but might not a very slight aurora be observable without the magnets being sensibly affected?

On the evening of the 4th the magnetic storm commenced about 2 P.M., and was at its height from 4 to 9, though the magnets were not steady again until after sunrise the next morning.

S. J. PERRY

Stonyhurst Observatory

I WRITE a very short account of the great aurora of February 4, as seen by me in the south-east of France, between Chambéry and Macon. It may be of some interest, as a brilliant aurora is very unusual in those latitudes, and this was quite comparable in brilliancy to the auroras of October 1870, and November 1871, which I witnessed in Scotland. The sunset was very clear and bright, but as the sunlight gradually faded, light fleecy clouds appeared in different parts of the sky, with the ruddy tints characteristic of the Northern Lights. As it became darker the redness increased in intensity and extent, overspreading a large portion of the sky, especially towards the zenith, and was streaked with bands of greenish white light. On the eastern horizon a well-defined arch of this pale green light was visible for some time, while underneath the arch the sky was so black that but for a large star shining in the centre of the blackness, I should have supposed that the darkness was due to a heavy cloud. There were, in fact, no true clouds at the time in the sky, and the large stars were everywhere visible amid the shifting masses of nebulous light, which at one instant seemed to be the ruddy reflection of a great fire, and at another to be lighted up by the rays of a full moon. Long streamers of red and green light seemed to shoot up towards the zenith from almost every point of the horizon at various times; but singularly enough there appeared to be fewer displays of this sort in the north than in any other quarter of the heavens. Being, however, in a railway carriage in motion,

and with mountains on every side, the true horizon was not visible, and it was impossible to make very accurate observations. The rosy clouds remained long after the coruscations had died away, but the chief splendour was displayed for an hour and a half after sunset.

If the aurora of this spring was not more brilliant than those of the last two autumns, it was, I think, more remarkable for its sharp contrasts of colour, and for the peculiar "coal-sacks," or areas of blackness, which seemed to be actually a part of the aurora as much as the red or green light.

DAVID WEDDERBURN

I HAVE to correct an important error in my account of the aurora of the 4th, published by you on the 8th. I stated that it was finest between 6 and 7. At 9 it appeared to be fading, and I ceased to watch it; but I learned afterwards that it rekindled, and was at its highest between 9 and 10. The colour was still red, and the columns of light met near the zenith.

Old Forge, Dunmurry, Co. Antrim, Feb. 12

The Great Comet of 1861

THE following observation may interest your readers. It is taken from a volume entitled, "The Industrial Progress of New South Wales," published by authority of the Colonial Government. Under the head of Astronomical Progress is a paper by Mr. Tebbutt, in which he says that, while observing in Australia on the morning of July 1, 1861 (*i.e.*, really, in the afternoon before sunset of our June 30), he noticed the widening out of the branches of the tail of the comet then visible. He remarks that this observation is very interesting when taken in connection with the announcement made by Mr. Hind, that "it appears not only possible, but even probable, that in the course of June 30, 1861, the earth passed through the tail of the comet, at a distance of perhaps two thirds of its length from the nucleus."

There were at least two observers in England of what was probably the opposite effect of perspective (*viz.*, the closing up of the branches of the tail) on the evening of June 30. The rapid, angular motion of one of the streamers was separately observed by Mr. George Williams, of Liverpool, and the Rev. T. W. Webb, of Hardwick, the latter of whom has given a detailed account of his observations in the "Monthly Notices of the Royal Astronomical Society," vol. xxii., p. 311. According to these observations, our actual passage through the streamers of the tail must have taken place about sunset on the evening of June 30.

A. C. RANYARD

ON LUMINOUS MATTER IN THE ATMOSPHERE

MUCH has lately been written and lectured on atoms, molecules, organic matter suspended in the air, effects of the light passing through the sky, abstracting its blue colour, and changing it into red. May I therefore be allowed to add some facts which I noticed during a long and careful observation of a hitherto almost unknown phenomenon to which my attention was drawn by chance.

Some years ago I had directed my excellent six-feet of Merz, Munich, towards the sun in order to draw the sun-spots in the camera-obscura. One day (April 27, 1863), when the sun had scarcely passed, and I was pushing the instrument to get its disc again in the field, I was astonished to perceive a mass of luminous little bodies, apparently coming from the sun, and passing altogether with great velocity towards the east. They brightened in a white and sparkling light, and were as numerous as stars; but as their velocity was much too great, and as they disappeared when I followed them to some distance from the sun, I was inclined to take them for little bodies floating in the atmosphere, and getting their light from the sun, an opinion which soon became stronger when I grew aware that I had to draw out the eye-piece some millimetres in order to get them quite clear

and distinct. As I had never heard of the existence of any such bodies, I resolved to give notice to Dr. Wolf, Director of the Observatory at Zurich, who convinced himself of the strange phenomenon, and, encouraging me to persist in my investigations, told me that the late Sig. Capocci, on the Capodimonte Observatory at Naples, had mentioned these little bodies appearing to him under similar circumstances on May 11, 1845. Since that time Prof. Dr. Edward Heis, of Münster, Westphalia, in his "Wochenschrift für Astronomie," 1869, March 24, also gave full corroboration to this fact. I therefore went on, and uniting the investigation to the daily labour of observing and drawing the sun-spots, my arrangement of the camera-obscura improved and ensured these results as well. Convinced of the importance of the phenomenon, I resolved to direct my whole attention to it, and to examine it thoroughly. I decided to find out not only the distance, the size, the shape, the frequency, the velocity, and the nature of the light of these little bodies, but also to take notice of their daily direction by comparing it with the simultaneous direction of winds and clouds. I continued my observations during a period of three years.

As I mentioned above, I was obliged to draw out the eye-piece of the telescope in order to have the little objects more distinct. Now, everybody knows that the focal distance of any lens, or system of lenses, such as the telescope is, will differ according to whether the beams come from a more or less distant object. The little bodies did not appear distinct in the focus of the sun; I had to draw out the eye-piece; but if the focal distance was greater, their distance was smaller than that of the sun, and by means of a scale placed on the eye-piece, I soon obtained the result that these little bodies belong to our atmosphere, floating in a stratum of about 4,000 metres down to about 200 metres, the most numerous swarm passing almost always at a distance of not less than 500 metres. Here I remark that for my observations I had chosen the time of the sun being in, or about, the meridian, for then I was sure to have its light as strong, and the sky as clear as possible, while mostly preferring a magnifying power of only 48 diameters.

Taking the little bodies in the right focus, I was enabled not only to draw their shape, which I found very various, but also to measure their apparent diameter, which did not differ less, and depended much on distance, the nearer ones being larger, and, as I learned from the scale the accurate distance of every one, I calculated their diameter to vary from 10 to 59 millimetres, the average being 32 millimetres. Their shape was very various, too. The greater number were oblong, angular, resembling flakes, some few were orbicular, while some smaller ones were star-shaped, with transparent arms.

With respect to their frequency, I was surprised to find on certain days, especially in April and May, an incalculable number of little bodies in the field of the instrument, passing without interruption for hours. In general I found their number to be connected with the purity of the sky; and every day I noticed the average, the daily minimum occurring in the morning and evening hours, the maximum in the noon-tide hours; also the annual minimums in the summer and winter months, the chief maximum from April 20th to May 15th, the second, much lower maximum in August and September. I often saw their number increase soon after clouds had passed.

The velocity of the bodies, irregular in the lower strata, being about 2 metres in a second, became greater and more regular in the higher ones, where, for instance, at a distance of 3,000 metres, I found them to pass 8 metres during the same period, a rapidity agreeing closely with that of the *cirri*, which often passed at or above this distance. Whether far or near, all these little bodies glittered in a magnificent white light behind the sky, but as it retreated farther from the sun its blue colour became darker, the light of the bodies consequently diminished, and was

more and more absorbed, when I followed them to some five or more degrees from the sun, in whose proximity they always brightened most, but passing over its disc, appeared to be rather dark, changing, however, suddenly into white when they emerged and entered the blue again. It became obvious that the little bodies I had before me were of small density, partly opaque, apparently of a white and reflecting surface, the edges of which were lit up by the sunbeams.

The course of the higher ones (at some 1,000 metres distance) being generally parallel, and their reciprocal velocity of about the same rate, I noticed much variety in the lower strata, where their flight was often of great inconstancy, changing their direction every moment, or falling, and second after second augmenting their focal distance, by the change of which, taken on the eye-piece scale, I learned that these bodies did not quite follow the law of gravitation, losing time; a fact not surprising to me, already convinced of their small consistency. In comparing the daily direction with the simultaneous course of winds and clouds, there was a remarkable conformity. Accepting the direction of the clouds to be the same as that of the wind in the stratum they pass through, a supposition not far from the truth, to which, of course, I was forced, having no weather-cock in such high regions, I found the direction of the little bodies and the clouds (in about the same stratum) to be (1) accurately the same in 31 per cent.; (2) differing not above 90 degrees in 49 per cent.; (3) differing not above 180 degrees in 67 per cent.; and (4) of quite opposite direction in only 15 per cent. This conformity is so evident that when the sky is cloudless, starting from the distance and direction of the ever-passing little bodies, one might easily learn the direction and perhaps the velocity of winds in the reciprocal strata, a fact of course of no little value to meteorologists and even mariners.

Taken altogether, these results could not but lead to the opinion that what I had to deal with were ice-crystals and flakes of snow. Here it may be recollected that already, in the seventeenth century, Mariotte, the renowned discoverer of the law of gas-expansion, pointed out that parheliions and mock-moons are caused by ice-crystals floating in the sky; and indeed, if we consider the above results, we are forced to believe him. Firstly, we learned that these bodies belong to the atmosphere; we also found them in its lower strata. Their average size of 32 millimetres, their flake-like shape, their incalculable number, will also strongly convince us. But while the minimum during the winter months might seem rather unaccountable, the chief maximum occurring in April and May, it may be remarked that from September to March the sun, although in the meridian, does not light up so strongly the rather misty sky; and that many days the sun will not appear at all. Now, referring to the chief maximum, from about April 20 to May 15, is it not astonishing that it occurs on the very same days which, especially those of May, were at all times well known from their low temperature, and called in Germany "the Latins" (Pancratius, May 12; Servatius, May 13, &c.), and were much feared by gardeners? But are the enormous masses of ice-crystals found in the atmosphere during these days the origin of its low temperature, or does the latter favour the formation of snow-masses? I only mention the fact that, for instance, heat is absorbed when snow is melting, and would be happy to direct the attention of meteorologists in any country to this phenomenon, inviting contributions of facts and correspondence. Finally, the velocity of the bodies being the same as that of the clouds, their reflected magnificent white light, their regular courses in the higher regions where strong winds are generally blowing, their irregular or even falling movement and small density in the lower ones, and their very remarkable conformity of direction with simultaneously passing clouds, will give much support to my explanation.

HENRY WALDNER

Weinheim, near Heidelberg

THE MONGOOSE AND THE COBRA

IN reading the interesting account of a fight between these two animals, as given in NATURE for Jan. 11 (p. 204), the question arises, How does the mongoose survive the bite of the cobra? There are only two solutions of this question, viz. :—(1) That the mongoose has some antidote; and (2) that it is not affected by the cobra poison. With regard to the first, various observers give different antidotes, such as grass, *Aristolochia*, &c. (see Sir J. E. Tennent's "Natural History of Ceylon," p. 38). There is no one plant that the mongoose has been proved to go to as a remedy. 2. That the mongoose is not poisoned by the bite of the cobra has, I think, been proved by Dr. Fayer, of Calcutta. I quote three of his experiments, which are published in the *Edinburgh Medical Journal*, April 1869, pp. 917-919:—"A young mongoose (*Herpestes Malaccensis*) was bitten two or three times by a full-grown cobra, at 1.24 P.M. on the 30th April 1868, on the inner side of the thigh from which the hair was first removed. Blood was drawn by the bites." This animal died in six minutes, but in the two following experiments no harm resulted to the mongoose. The second mongoose was also "bitten on the inner side of the thigh, and put into a cage immediately." It got no antidote except "raw meat," and was none the worse for the bite. The third mongoose was put into a large wire cage with a full-sized cobra at 1 P.M. (April 2, 1868). "The snake struck at the mongoose, and they grappled with each other frequently, and apparently the mongoose must have been bitten, as the snake held on to it about the neck or head. At 1.15 P.M. there was no effect on the mongoose; both it and the snake were much excited and angry, the snake hissing violently. 2.30; no effect on the mongoose. The snake is bitten about the head, and shows the bleeding wounds. 2.51; they are both occasionally darting at each other, but the mongoose jumps over the snake, and tries to avoid it. Next day at noon both were well; the snake frequently struck at the mongoose, but did not appear to injure it; both seemed very savage, but the mongoose would not bite the snake; he jumped over it. There had been two cobras in the cage during the night, both equally fierce, and striking each other and the mongoose; but the latter was uninjured. He was bitten once by the cobra rather severely on the head." JAMES W. EDMONDS

HARTWIG'S SUBTERRANEAN WORLD *

THE increasing demand for works of a semi-scientific character similar to that now under consideration, is in itself the most satisfactory proof that a desire for acquiring a more extended and accurate knowledge of the phenomena of Nature is gradually taking root within a

FIG. 1.—Blind Fish (*Amblyopsis spelæus*)

class of society, which, until of comparatively late years, had always contented itself with a very opposite style of literature. When it is observed, in many of the so-called popular scientific books, that accuracy has evidently been less

* "The Subterranean World." By Dr. George Hartwig. (London: Longmans, Green, and Co.)

carefully studied than what is termed sensational effect—a feature so characteristic of the period we live in—it is refreshing to find that Dr. Hartwig, in his description of the various phenomena of the subterranean world, has, without any such aid, succeeded admirably in conveying a vast amount of solid information, in so lucid and easy a style as to make even his unscientific readers quite interested, and likely to forget that he is treating of subjects

usually considered as pertaining to the domain of dry Science. In so doing he seems also to have been assisted by having adopted a system of classification, or rather grouping, of the subjects which form his separate chapters, which, although not strictly scientific, is preferable in the present instance, as being more in accordance with popular notions.

The work, besides being well got up, is abundantly

CARBONIFEROUS FOREST, CARBONIFEROUS PERIOD

illustrated; many of the woodcuts being of very superior character and execution, whilst the plates are, in general, good, and with one exception—that of the ideal view of the great earthquake at Lisbon in 1775—they are free from that objectionable sensational or exaggerated character so observable in the illustrations of French works

on popular Science, several of which have lately been rendered into English. The two maps indicating the distribution of coal and metallic deposits in Great Britain and the Americas respectively are not on a par with the rest, owing to errors of omission; thus, amongst others, neither the central lead-producing district of Wales, nor

the Northampton iron district, are shown in the former ; nor have the auriferous deposits of Central America or British Columbia been indicated on the latter map.

In a work intended for the general British public, the temperature, when alluded to, should preferably have been stated in degrees of Fahrenheit's thermometer, since, al-

though the scale of Celsius or centigrade is often made use of by men of science here, it will not be at all familiar to the majority of the readers of Dr. Hartwig's book, which it is to be hoped will have a very extended circulation. Several errors in the text might also be pointed out—as, for example, calling the usual Cornish ore or copper

INDIAN ROCK-CUT TEMPLE: PORCH OF THE CHAITYA CAVE TEMPLE, AJANTA

pyrites a bisulphuret of copper ; titanium is stated to be a metal of a copper red colour, &c. ; but when the great extent of scientific ground over which the author travels in this book is taken into consideration, some allowance must be made, and it must fairly be admitted that the work, as a whole, is singularly free from serious errors,

and we would recommend it strongly, in the belief that from its at once easy entertaining and instructive style, it will be sure to interest many in the study of these natural phenomena, to whom the very name of Science is at present associated with all that is dry and uninviting.

D. F.

RECENT DISCOVERY OF PIT-DWELLINGS

DURING the late summer, while engaged in excavating a Roman building at Finkley, near Andover, a deep trench, 100 feet in length, was found, dilating at the opposite ends into large subterranean pits, which, from the primitive character of the articles met with in them, such as flint and bone implements, spindle-whorls of chalk, and a rude form of pottery, appeared to belong to an earlier period than the Roman. One of the labourers engaged in the explorations became quite an expert in the recognition of these rude objects; and he having lately been employed in digging a yard at a new railway station, situated on a hill, about half a mile distant from St. Mary Bourne, immediately overlooking the Upper Test Valley, found the subsoil so abundant in calcined stones, broken pottery, and other evidences of early occupation, that he called my attention to the circumstance, which led to the discovery of a group of pit-dwellings or hut-circles; and it is likely, from their mode of arrangement, that they form a portion of an extensive settlement or *vicus*. Some knowledge of nine of these has been obtained, although, from their situation, two only have been completely investigated, and five others partially.

The pits occupy the space of about a quarter of an acre, and have all entrance shafts, sloping gradually downwards from their inlets, and widening as they approach the pits. They may, with their contents, be described *seriatim*. No. 1 is oval or pear-shaped, having its entrance southwards. Its length is 22 feet from the end of the pit to the mouth of the alley; greatest diameter 12 feet; depth at the centre of the pit 5 feet. This was the only circle that contained flints, of which twelve cartloads were removed from it; and as some of the stones were arranged in courses, without mortar, around its circumference and on each side of the alley, I have thought that the superstructure must have been of flint, and had fallen in. The relics found were chiefly at the centre, where the fire-place had evidently been; the smoke most likely escaping through the centre of the roof. They consisted of about a bushel of calcined flints, bones of a small species of *Bos*, probably *longifrons*, *Cervus elephas*, *Capra*, *Sus*, and *Canis*, besides broken vessels, chiefly of a very rude, hand-made kind, although a few pieces found about the pits bore wheel-marks. The bones had mostly been split open in order to obtain their marrow. They had further been exposed to fire, and bear impressions made by teeth and knives; and some of the smaller long bones had evidently been used as marrow-spoons, while other small splinters of bone had the appearance of having served the purpose of awls or needles. In this circle also a part of a rude sandstone hand grain-rubber was found, besides some flint-flakes, a scraper, and some cores; and, in addition, the outer lip of a large cowl, which had been carefully cut from the shell, and had been used as a rasp, the crenulations in the lip being considerably worn down. It had further been employed as a polisher apparently, the enamel being worn away in places.

Pits 2 and 3 were only partially explored, as they extended beneath the station yard. One of them, however, was partly filled with calcined flints; and in it were found a piece of a grain-rubber and pottery and bones similar to those just described.

Pits 4 and 5 had only portions of their passages opened, as the pits extended beneath the Station Road. In these we found a few flint-flakes, and some calcined stones.

Pit 6 contained no remains, as it was evidently the passage only of a pit partly formed, and had not been occupied.

In digging a well in the station garden similar relics were thrown out, and it is evident that the shaft of the well passed through one of these pits; and, as additional evidence of British occupation, in clearing away the soil around the circles, one of the labourers picked up a Gaulish

gold coin, which bears on its obverse and reverse degraded representations of more perfect figures. The coin, in short, is a slightly more perfect copy of the lowermost of the three coins depicted at p. 84 of "The Celt, the Roman, and the Saxon," 1st. ed.; which figure is there stated as being a rude copy of a gold stater of Philip of Macedon.

Pit 7 was fully explored. It was 42 ft. in length from the extremity of the pit to the mouth of the passage, which opened eastward; its widest diameter 13 ft. 6 in., and depth 5 ft. at the pit's centre. Here the fire-place had stood, as in No. 1, and around it we found bones similar to those discovered in Pit 1, with the addition of some teeth of a small species of horse, and bones of the hare or rabbit. The bones were, in most cases, broken, and some of them had been wrought for use as implements. Two flint arrow-heads were found in the alley, and the centre of the circle further contained flint-flakes, scrapers, cores, and arrow-heads, a fragment of a rude grain-rubber, and a flint muller showing use on one side. Here also occurred a whetstone, made from a piece of sandstone such as I have observed occurring in the drift of the Reading beds; and evidently from the same drift a lump of native ironstone, containing a large percentage of iron, which had been picked up by some occupant of the pit and used as a hammer. As throwing some small light on their domestic economy, a chalk spindle-whorl was found, and with it a small disc of pottery, bored at the centre, the direction of the hole showing that it had been suspended by a string, perhaps round its owner's neck. The whole of the fettle ware found here was of a rude hand-made type, and some of the "corks" were scored with irregular zigzag lines, made apparently with a pointed stick.

At nine feet south of Pit 7 a circular hole in the chalk was cleared out. It was found to be 5 ft. in diameter and 3 ft. in depth. It contained a quantity of bones of animals similar to those already enumerated, with snail shells that had been exposed to fire; and beneath the bones a number of charred flints, with charcoal and ashes. It was evident that strong fire had been employed here, as the chalk was in places burnt through and discoloured to the depth of several inches, which led to the inference, coupled with its contiguity to Pit 7, that it was a cooking-hole. It is not unusual for uncivilised people, as the negroes, to have their cooking places outside their dwellings (see "Flint Chips," by E. T. Stevens, p. 59).

At another part of the same yard, about 10 ft. of well-built wall was removed. It was doubtless Roman, as near it a better kind of pottery was found, including a piece of Samian, besides two roof-nails and a bronze buckle.

The quantity of calcined stones everywhere present was the most striking feature in the remains. Some of them, I observed, were faced on one side, and a few had facets at right angles, and these, it occurred to me, might have been used in constructing ovens or fire-places. A large number, however, were perfectly circular, and had bright, clean surfaces; these might have been employed for the purpose of stone-boiling.

With traces of Roman occupation we have here these rude remains which show residence by an earlier people, who, doubtless, lived on after the advent of the Romans. I have, as yet, observed no entrenchments in the field; but there is no doubt that similar circles occupy a large space of the upper slope of the valley. The flint implements stamp the remains as Neolithic; and those found in the pits differ in no respect from the wrought flints occupying the subsoil of the yard, as well as occasionally occurring on the surface of the adjoining fields. The settlement is favourably situated to have enabled the occupants to obtain water from the river Test; and along the same side of the valley, within the space of two miles, I have discovered more than one working site, in which I have obtained a large and varied collection of tools and weapons both chipped and polished.

These huts must have been covered, some, perhaps, with stones, others with a wooden or wattle superstructure, covered with clay or sods of turf; and their poor inhabitants evidently cultivated, to a small extent, some of the cereals, had an early knowledge of weaving, and lived domesticated with oxen, goats, and swine. The red-deer were most likely obtained by hunting in the dense forest that then occupied the deep clay lands of North Hampshire, as an extension of the ancient forests of Harewood, and Chute, and Finkley. Further, these shallow pits might have been the summer residences of a people whose winter habitations were at Finkley.

J. STEVENS

INAUGURATION OF THE OBSERVATORY AT CORDOBA

AN interesting account of the inauguration of the Argentine Observatory at Cordoba in October last appears in the *Standard* of Buenos Ayres. The chief feature of the ceremonial was a very able address by Prof. Gould, the Director, from which we make the following extracts, as bearing specially on the work of the observatory:—

"In the year 1751 a French astronomer, the Abbé de la Caille, visited the Cape of Good Hope for the purpose of determining the positions of the principal southern stars. With a little telescope of comparatively insignificant dimensions, he succeeded in obtaining the materials for so complete a catalogue—as far as the limit of brightness which his telescope permitted—and in determining the positions of those stars so well, that this catalogue of about 9,800 stars constitutes to-day the chief reliance of astronomers for their knowledge of a large portion of the southern sky. Since that time a permanent observatory has been established by the British Government at the same place, and a large number of valuable observations have been made by various eminent men. Other observatories in the southern hemisphere have been founded at Paramatta, Santiago de Chile, and Melbourne, all of which have contributed essentially to our knowledge of the southern sky; as also has the observatory at Madras, which, although north of the equator, commands a view of the greater portion of the southern heavens. Yet how much remains to be done in this direction will be very evident when I state that, while the number of stars in the northern hemisphere whose positions and magnitudes have been determined cannot fall short of about 330,000, the number in the southern hemisphere whose observed places have been published does not probably exceed 50,000. But this is not all. The greater portion of those which have been observed lie in that part of the sky which is clearly visible in Europe; and if we consider the regions beyond 30°, there are scarcely 13,000 southern stars whose places and magnitudes have been determined and made available for scientific use, while the corresponding portion of the northern sky contains something like 164,000 such stars.

"The first undertaking now proposed for the Argentine Observatory is to do something towards filling this hiatus by determining the places of the principal stars situated between the tropics, where the observations of northern astronomers begin to become less numerous, and the polar circle, where Gilliss' observations commence. This work is best performed by dividing the sky into narrow zones or belts, and subjecting each zone to a special scrutiny for the purpose of measuring the positions of all stars of a sufficient brightness within its limits. If no unforeseen impediment presents itself, these observations should be completed within two years from their commencement.

"There is another most important investigation especially desirable in the present condition of our knowledge: this is the application of the newly-discovered methods of

stellar photography to the more prominent objects in the southern heavens. The ingenious researches and inventions of Mr. Rutherford in New York have resulted in the development of methods by which the relative positions of clusters of stars may be permanently recorded by photographing them upon glass, and the numerical values subsequently determined by means of a measurement of the photographic impressions, with a degree of precision far greater than that of the ordinary methods. And this process possesses the signal and peculiar advantage, that the representations thus obtained of the stars' places at a given moment may be preserved, and the measurements repeated at any subsequent time. The process has not yet been introduced into European observatories, but it has been thoroughly tested in America, and valuable researches have already been made by this photographic method.

"During the greater part of the year we have had neither instruments nor building, and during the short time these have been available we have experienced an unexpected and most serious obstacle in the clouds of impalpable dust, which, rising from all sides, penetrate to the inmost crevices of every part of the instruments. This difficulty will, I think, be obviated to a great extent when vegetable growth shall have covered the soil; and to this end the Minister has given directions for providing as good a supply of water as may be possible, while the building and instruments have been provided with special and unusual protections against the evil. The position of the city of Cordoba renders this trouble inevitable, inasmuch as water for irrigation is only to be found in the valley, whilst an observatory must necessarily be placed upon high land. With the arrival of the rainy season I trust that a carpet of vegetation may remove this source of anxiety.

"A considerable time would, under any circumstances, have been requisite for computing the numerical table, and making the various other calculations needful for bringing the instruments into active service. The additional interval has been employed in an undertaking of a totally different sort, which may, I trust, be found in the end to possess as much scientific importance as the work originally intended. During this period of enforced delay we have succeeded in making a full catalogue of all those stars of the southern heavens which are visible to the naked eye, determining for each one the precise degree of its brightness. When, after the moon has set to-night, you raise your vision to the starry sky, and, as you look more intently, perceive one faint star after another reveal itself to your sight, you will yet succeed in discerning no star whose place and magnitude has not been recorded within the past year by some one or more of the observers in this institution—

"*'Sidera cuncta notans tacito labentia cælo.'*"

"The progress of the work so far has not failed to afford its due share of discoveries. It has given us the knowledge of a considerable number of stars which possess the singular character that their brightness is not always the same, but undergoes systematic variations. Some have been seen to rise to considerable brilliancy, and then fade away until telescopes of some power are needed for rendering them visible. Others still are now found to possess a brilliancy decidedly greater or decidedly less than that which has been assigned to them by more than one astronomer in times past. Such stars must be carefully watched, and the fact of any regular and periodic fluctuation in the amount of their light either established or disproved. Of such cases there are already many on our records, thanks to the assiduity and zeal of the assistant astronomers, no one of whom has failed to make manifest the existence of several. One of those most remarkable for the rapidity of its changes is a little star in the constellation "Mæa," which is invisible to the unaided

sight during one half its period, and visible during the other half; while the observations of Mr. Rock show that it goes through all its changes within the short interval of 21½ hours. Another in the constellation of the "Southern Triangle," which has been regularly observed by Mr. Davis, exhibits regular fluctuations of light, comprised within a period of about 3½ days, similarly alternating between visibility and invisibility. These two exhibit the most rapid changes of any of the stars which we have hitherto observed; but there are others not less interesting, observed not only by the two gentlemen mentioned, but also by Messrs. Thorne and Hathaway, who are likewise pursuing these investigations with much success."

NOTES

THE retirement of Prof. Huxley from the London School Board throws a great responsibility upon the men of Science in London in general, and on Marylebone in particular. We are of opinion that of all the good work which Prof. Huxley has done, none will have a more lasting national importance than that which has resulted in the introduction of Science among the subjects to be taught in the London schools—and, therefore, in all the School-Board-schools throughout the country, for the force of public opinion will, in the long run, insist that the London model shall be everywhere followed. It is because we fear that this important advance may be arrested, unless steps are taken still to have the claims of Science represented on the Board, that we draw attention to the subject, which, in our opinion, is of sufficient importance to occupy the attention of the Royal Society, and the other scientific bodies, if their aid is necessary. Doubtless membership of the School Board involves sacrifice; but it is to be hoped that the clerical squabbles which have so interfered with the desired progress here, as it did, ineffectually, in other countries, are now as nearly over as they ever will be; and if this be so, then, instead of the 170 sittings given by some members last year, a much smaller number will suffice.

WE have reason to know that many weak people have been alarmed, and many still weaker people made positively ill, by an announcement which has appeared in almost all the newspapers, to the effect that Prof. Plantamour, of Geneva, has discovered a comet of immense size, which is to "collide," as our American friends would say, with our planet on the 12th of August next. We fear that there is no foundation whatever for the rumour. In the present state of science nothing could be more acceptable than the appearance of a good large comet, and the nearer it comes to us the better, for the spectroscope has a long account to settle with the whole genus, which up to this present time has fairly eluded our grasp. But it is not too much to suppose that the laymen in these matters might imagine that discovery would be too dearly bought by the ruin of our planet. Doubtless, if such ruin were possible, or indeed probable—but let us discuss this point. Kepler, who was wont to say that there are as many comets in the sky as fishes in the ocean, has had his opinion endorsed in later times by Arago, who has estimated the number of these bodies which traverse the solar system as 17,500,000. But what follows from this? Surely that comets are very harmless bodies or the planetary system, the earth included, would have suffered from them long before this, even if we do not admit that the earth is as old as geologists would make it. But this is not all. It is well known that some among their number which have withal put on a very portentous appearance are merely the celestial equivalents of our terrestrial "wind-bags"—brought down to their proper level they would have shrunk into very small dimensions indeed. But there is more comfort still. The comet of 1770 positively got so near to Jupiter that it got entangled among his moons, the diameter of the smallest of which is only some 2,000

miles; but the moons pursued their courses as if nothing had happened, while the comet was so discomfited by the encounter that it returned by another road—i.e. astronomically speaking, its orbit was entirely changed. While, last of all, in our correspondence this week, will be found one fact the more in favour of the idea that, in 1861, we actually did pass through a comet. We have a suggestion for those weak people who are still alarmed by these celestial portents, and steadily refuse to acquaint themselves with the most elementary work on Astronomy, which would convince them how groundless their fears are. In India, during the last Eclipse, the priests reaped magnificent harvests from the offerings of the faithful. In England; possibly, it would be considered incorrect to make such offerings to the priest; but let them still be made—to the Royal Astronomical Society. In this way the English Philistine would approach nearer the standard of his less-civilised brother; Science would be benefited, and, doubtless, the omen would be averted—at all events they always have been.

THE Anniversary Meeting of the Royal Astronomical Society was held on Friday last, when the president's address was read. The medal this year has been awarded to Prof. Schiaparelli for his brilliant demonstration of the identity which exists in the elements of the orbits of certain comets and known systems of meteors. Among the obituary notices for the year were those of Sir John Herschel, Prof. De Morgan, and Mr. Babbage.

THE Council of the Geological Society have awarded the Wollaston Medal for the present year to Prof. J. D. Dana, of Yale College, Connecticut, and the balance of the proceeds of the Wollaston Fund to Mr. James Croll, of Edinburgh.

THE Hopkins Prize, which was founded in memory of the late Mr. Hopkins, and is adjudged to the author of the best original memoir, invention, or discovery in connection with Mathematico-physical or Mathematico-experimental Science that may have been published during the three years immediately preceding (who is or has been a member of the University of Cambridge) has been awarded to Prof. J. Clerk Maxwell, F.R.S. The adjudicators were Profs. Stokes, Tait, and Clifton. The fund is vested in the Cambridge Philosophical Society.

WE learn that, in addition to the scholarships for Natural Science at Cambridge, of which a list was given in our number for February 1, King's College offers an exhibition of the value of about 80*l.* per annum. The examination will commence on April 9, will include Physics, Chemistry, and Physiology, with one Classical and one Mathematical paper, and will be open to all candidates under twenty, and to undergraduates of the college in their first and second year. Names must be sent in, before March 10, to the Rev. A. A. Leigh, tutor of the college, from whom further information may be obtained.

PROF. GEORGE ROLLESTON has been elected a Fellow of Merton College, under the ordinance of 1854, which founded the Linacre Professorship of Physiology, and endowed it out of the revenues of this college. Prof. Rolleston graduated in 1850, and was afterwards elected Fellow of Pembroke College. In 1860 he was appointed to the Linacre Professorship of Physiology.

THE Industrial Museum at Edinburgh has lost, by the death of J. Boyd Davies, its zoological director or manager. No one knows what the authorities are going to do, but it is to be hoped they will select a good man, not a talker but a worker. The monetary value of the post is 200*l.* to 250*l.* per annum. The Lectureship on Zoology at the High School is also vacant.

AT a meeting of the Royal Geographical Society held on Monday evening last, the president, Sir H. C. Rawlinson, stated that, three days before, the expedition, consisting of Lieut. Dawson, R.N., Lieut. Henn, R.N., and Mr. Oswald Livingstone, the son of Dr. Livingstone, set sail in the first steamer despatched

from the Thames to Zanzibar direct. The three gentlemen engaged in it had been given every assurance that their undertaking would be assisted at home in every possible way. The subscriptions to the fund for its maintenance amounted to 5,000*l.*, of which upwards of 2,000*l.* was received from London alone; Edinburgh had contributed 350*l.*; and the little town of Hamilton, the native place of Dr. Livingstone, 200*l.*; while the corporation of the City of London had subscribed one hundred guineas, and the leading commercial firms of the City had come forward in an equally liberal manner. The Admiralty has refused to allow Lieut. Dawson his full pay while engaged on the expedition.

THE important article which we are able to give this week, on the Position of the Centre of Gravity in Insects," by M. Felix Plateau, is an abstract of a long memoir by that author, to be found in the "Bibliothèque Universelle, Archives des Sciences Physiques et Naturelles," vol. xliii, for 1872.

THE *Naval and Military Gazette* asserts that the *Challenger*, screw corvette, will be commissioned early in the summer for a voyage of exploration and research. Some scientific gentlemen will be accommodated on board the vessel, and it is probable that Captain George S. Nares, now serving in the surveying vessel *Sharwater*, in the Red Sea, will be placed in command. The actual places which will be visited have not yet been determined, but it is anticipated that the groups of islands in the Pacific will have special attention bestowed upon them. This movement on the part of the Admiralty is in encouraging contrast to the fact that Arctic voyages have been abandoned to other nations, and to the late refusal of the Lords of the Treasury to grant any assistance whatever to the Livingstone search expedition.

The following is the list of officers and council of the Royal Microscopical Society elected on the 7th of February:—President—Mr. W. K. Parker, F.R.S. Vice-Presidents—Dr. W. B. Carpenter, F.R.S., Dr. J. E. Gray, F.R.S., Sir John Lubbock, Bart., M.P., F.R.S., Mr. John Millar. Treasurer—Mr. John W. Stephenson. Secretaries—Mr. Henry J. Slack, Mr. Jabez Hogg. Council—Dr. Robert Braithwaite, Mr. John Berney, Mr. Charles Brooke, F.R.S., Mr. T. W. Burr, Dr. W. J. Gray, Dr. Henry Lawson, Mr. Henry Lee, Mr. S. J. McIntire, Mr. Henry Perigal, Dr. G. W. Royston-Pigott, Mr. Charles Stewart, Mr. T. C. White.

THE International Scientific Series, to be published by Henry S. King and Co., is an indication of a movement of great importance. The series will be published simultaneously in New York by Messrs. D. Appleton and Co., in Paris by M. Germer Baillièrre, and in Leipzig by Messrs. Brockhaus. The first volume, by Prof. Tyndall, F.R.S., on "The Forms of Water, in Clouds, Rain, Rivers, Ice, and Glaciers," is now in the press, and will be published in March next. Among others already arranged for are Prof. T. H. Huxley, F.R.S., on Bodily Motion and Consciousness; Dr. W. B. Carpenter, F.R.S., on the Principles of Mental Physiology; Sir John Lubbock, Bart., F.R.S., on the Antiquity of Man; Prof. Rudolph Virchow, on Morbid Physiological Action; Prof. Alexander Bain, on Relations of Mind and Body; Prof. Balfour Stewart, F.R.S., on the Conservation of Energy; Mr. Walter Bagehot, on Physics and Politics; Dr. H. Charlton Bastian, F.R.S., on the Brain as an Organ of Mind; Mr. Herbert Spencer, on the Study of Sociology; Prof. William Odling, F.R.S., on the New Chemistry; Prof. W. Thiselton Dyer, on Form and Habit in Flowering Plants; Dr. Edward Smith, F.R.S., on Food and Diets; Prof. W. Clifford, on the First Principles of the Exact Sciences explained to the non-mathematical; Mr. J. N. Lockyer, F.R.S., on Spectrum Analysis; Dr. W. Lauder Lindsay, on Mind in the Lower Animals; Dr. J. B. Pettigrew, F.R.S., on Animal Locomotion;

Prof. A. C. Ramsay, F.R.S., on Earth Sculpture; Dr. Henry Maudsley, on Responsibility in Disease; Prof. W. Stanley Jevons, on the Logic of Statistics; Prof. Michel Foster, on Protoplasm and the Cell Theory; Rev. M. J. Berkeley, on Fungi: their nature, influences, and uses; Prof. Claude Bernard, on Physical and Metaphysical Phenomena of Life; Prof. A. Quetelet, on Social Physics; Prof. H. Sainte-Claire Deville, Introduction to General Chemistry; Prof. Wurtz, on Atoms and the Atomic Theory; Prof. Quatrefages, on the Negro Races; Prof. Lucaze-Duthiers, on Zoology since Cuvier; Prof. Berthelot, on Chemical Synthesis.

THE death of Dr. Harvey, Professor of Botany in the University of Dublin, arrested the progress of the *Flora Capensis* shortly after the publication of the third volume had brought the work half-way towards its completion. It is hoped that if the Cape Legislature will accede to Dr. Hooker's request for a renewal of the grant towards the expenses of printing, the remaining volumes may be at once taken in hand. The general supervision will be undertaken by Prof. Thiselton Dyer, who will probably receive assistance in monographing different families from Profs. Lawson and Perceval Wright, Drs. Sonder, Trimen, Masters, and MacNab, and from Messrs. Carruthers, A. W. Bennett, Hiern, Britten, and Baker.

DR. MILLER COUGHTREY is engaged on a long paper on the long-handled combs, Roman, Swiss, bone cave, Mexican, and other forms. It is now in proof for the Proceedings of the Antiquarian Society of Scotland.

WE note the appearance of the first number of a new monthly magazine, "The Earth: a popular magazine on Geology," whose object is "to collate and bring together facts and discoveries bearing on advanced and truthful views of Geology, and to oppose false and current opinions on the subject." Among the fallacies to be exposed are:—"That there has been an evolution of one creature into another," "that vegetable life either preceded or succeeded animal life on the globe," "that granite is a rock of fusion," &c.; and among the truths to be advocated are:—"That the configuration of the earth is a result of the agency of the winds and tides, of volcanic action, and of fluvial and glacial action," "that there has been no evolution of species," and "that basalt is a crystallisation from solutions."

WE are glad to see that the labours of the English Strasburg Library Committee, consisting of Mr. Hepworth Dixon, Lord Houghton, Prof. Huxley, Lord Lytton, the Duke of Manchester, Sir J. G. Tollemache Sinclair, Bart., M.P., and Mr. Trübner, secretary, are being crowned with success. From the list we have just received of books already presented, we see that almost every department of Government has presented its publications. This remark also applies to the following scientific societies:—The University of Oxford, the Trustees of the British Museum, the Astronomer Royal, the Royal Geographical Society, the Royal Society of Edinburgh, the Botanical Society of Edinburgh, the Early English Text Society, the Historic Society of Lancashire and Cheshire, the Meteorological Society, the Radcliffe Observatory, Oxford, the Royal United Service Institution, the Philosophical Society of Glasgow, the Royal Institution of Great Britain, and Owens College, Manchester. In this list we may remark that some of the most important of our societies are still conspicuous by their absence.

THE problem, "What to do with our juvenile criminals," appears to have been solved by the Government of the State of New York in a most satisfactory manner. We have before us, and hope to be able to return to it again, a pamphlet issued by the "Department of Public Charities and Correction," bearing the title, inexplicable to English bumbledom, of "Cruise of School-ship *Mercury* in Tropical Atlantic Ocean." It is, in fact, an account of a cruise undertaken in the interests of science,

and under the management of Prof. Henry Draper, containing a report "on the chemical and physical facts collected from the Deep Sea Researches made during the voyage of the nautical school-ship *Albatross*, undertaken in the Tropical Atlantic and Caribbean Sea in 1870-71; the "cruisers" being, not Dr. Carpenter, Prof. Wyville Thomson, and Mr. Gwyn Jeffreys, but the boys committed to the care of the Commissioners in New York for slight misdemeanours and vagrancy!

We regret to hear that the Geology Class at Christ's Hospital, having gone through an introductory course of lectures, has stopped, and has not been replaced by a class of Botany or any sister science. It is greatly to be regretted that the Chemistry Class do not get beyond the simpler metals and easy testing; those who would wish to study Chemistry are restricted to the more elementary branches of inorganic chemistry alone.

PROF. HUGHES, F.R.G.S., gave two lectures at Christ's Hospital on February 3 and 10 on Physical Geography. In his introduction he, like Prof. Huxley, claimed for his science a position equal to that held by the German *Erdkunde*, defining both to be that which explained to us "the aspect of nature and natural phenomena." In his first lecture he dealt with "High Lands and Table Lands," somewhat overthrowing the popular idea of mountains gained from text books. In his second lecture he spoke of the "Ocean and Deep-Sea Currents," explaining clearly and advocating warmly the ingenious theories and proofs of Dr. Carpenter, about which there has been so much discussion in the pages of NATURE. We attach no little importance to these lectures, because they brought the hearers up to the present state of our knowledge of the deep sea and of the Himalayan Mountains, far further than the best text-books have yet brought us. It is only to be regretted that other gentlemen of like abilities and knowledge with Prof. Hughes do not come forward and offer to lecture to boys on other branches of Natural Science. It is hard for those who feel an interest in nature to feel themselves bound by the iron chains of verse composition.

Lippincott's Magazine for January contains an interesting and profusely-illustrated article on the New Port Storm Signals, by Prof. Thompson B. Maury.

PHYSICS

Preliminary Catalogue of the Bright Lines in the Spectrum of the Chromosphere*

THE following list contains the bright lines which have been observed by the writer in the spectrum of the chromosphere within the past four weeks. It includes, however, only those which have been seen twice at least; a number observed on one occasion (Sept. 7) still await verification.

The spectroscope employed is the same described in the Journal of the Franklin Institute for November 1870; but certain important modifications have since been effected in the instrument. The telescope and collimator have each a focal length of nearly 10 inches, and an aperture of $\frac{1}{2}$ of an inch. The prism-train consists of five prisms (with refracting angles of 55°) and two half-prisms. The light is sent twice through the whole series by means of a prism of total reflection at the end of the train, so that the dispersive power is that of twelve prisms. The instrument distinctly divides the strong iron line at 1961 of Kirchhoff's scale, and separates B (not b) into its three components. Of course it easily shows everything that appears on the spectrum maps of Kirchhoff and Angström. The adjustment for "the position of minimum deviation" is automatic; i.e., the different portions of the spectrum are brought to the centre of the field of view by a movement which at the same time also adjusts the prisms.

* Reprinted from the *American Journal of Science and Arts*.

The telescope to which the spectroscope is attached is the new equatorial recently mounted in the observatory of the College by Alvan Clark and Sons. It is a very perfect specimen of the admirable optical workmanship of this celebrated firm, and has an aperture of 9 $\frac{1}{2}$ inches, with a focal length of 12 feet.

In the table the first column contains simply the reference number. An asterisk denotes that the line affected by it has no well-marked corresponding dark line in the ordinary solar spectrum.

The second column gives the position of the line upon the scale of Kirchhoff's map—determined by direct comparison with the map at the time of observation. In some cases an interrogation mark is appended, which signifies not that the existence of the line is doubtful, but only that its precise place could not be determined, either because it fell in a shading of fine lines, or because it could not be decided in the case of some close double lines which of the two components was the bright one; or, finally, because there were no well-marked dark lines near enough to furnish the basis of reference for a perfectly accurate determination.

The third column gives the position of the line upon Angström's normal atlas of the solar spectrum. In this column an occasional interrogation mark denotes that there is some doubt as to the precise point of Angström's scale corresponding to Kirchhoff's. There is considerable difference between the two maps, owing to the omission of many faint lines by Angström, and the want of the fine gradations of shading observed by Kirchhoff, which renders the co-ordination of the two scales sometimes difficult, and makes the atlas of Kirchhoff far superior to the other for use in the observatory.

The numbers in the fourth column are intended to denote the percentage of frequency with which the corresponding line is visible in my instrument. They are to be regarded as only roughly approximate; it would of course require a much longer period of observation to furnish results of this kind worthy of much confidence.

In the fifth column the numbers denote the relative brilliancy of the lines on a scale where 100 is the brightest and 1 the faintest. These numbers also, like those in the preceding column, are entitled to very little weight.

The sixth column contains the symbols of the chemical substances to which, according to the maps above referred to, the lines owe their origin.

There are no disagreements between the two authorities; in a majority of cases, however, Angström alone indicates the element, and there are several instances where the lines of more than one substance coincide with each other and with a line of the solar spectrum so closely as to make it impossible to decide between them.

In the seventh and last column the letters J., L., and R. denote that to my knowledge the line indicated has been observed and its place published by Janssen, Lockyer, or Rayet. It is altogether probable that a large portion of the other lines contained in the catalogue have before this been seen and located by one or the other of these keen and active observers, but if so I have as yet seen no account of such determinations.

I would call especial attention to the lines numbered 1 and 82 in the catalogue; they are very persistently present, though faint, and can be distinctly seen in the spectroscopie to belong to the chromosphere as such, not being due, like most of the other lines, to the exceptional elevation of matter to heights where it does not properly belong. It would seem very probable that both these lines are due to the same substance which causes the D³ line.

I do not know that the presence of titanium vapour in the prominences and chromosphere has before been ascertained. It comes out very clearly from the catalogue, as no less than 20 of the whole 103 lines are due to this metal.

Hanover, N.H., Sept 13, 1871

C. A. YOUNG

SCIENTIFIC SERIALS

The *American Naturalist* for October 1871 commences with a paper by Dr. Jeffries Wyman entitled, "Experiments with Vibrating Cilia," the chief points in which are some determinations of the rate of movement of the vibrating cilia on the gills of Mollusca, both in air and in water, and the description and drawing of an instrument by means of which this rapidity can be measured and exhibited so as to be seen over a large lecture-room. Prof. James Orton furnishes some contributions to the Natural History of the Valley of Quito (continued in the next number); and Dr. J. S. Billings contributes a paper on *Hysterium*, a genus of Ascomycetous Fungi, and some of its allies, illustrated by a plate. Mr. T. Martin Trippie has a very interesting paper on some differences between Eastern and Western Birds, in which he traces the difference in habits, note, time of breeding, &c., in the same species of bird in the eastern and newly-settled western portions of the American continent, and the manner in which the indigenous avifauna of the Western States is becoming gradually superseded by eastern forms, along with the advance of man.

The first paper in the number for November is by Grace Anna Lewis on Symmetrical Figures in Birds' Feathers, in illustration of the beauties furnished for the microscope by the feathers of birds. Dr. Elliott Coues gives a description and drawing of a little-known species of oriole, the only one which is a native of the Western States, and is known as Bullock's Oriole, *Xanthorhynchus bullockii*, Swainson. Prof. George H. Perkins contributes some "Notes on the Geodes of Illinois;" and the remainder of the number is occupied by reviews, and the usual interesting items of Natural History Miscellany.

The number for December opens with an extremely interesting paper by the Editors on "The Mammoth Cave and its Inhabitants," an account of a visit paid to this extraordinary cavern in a hill of the sub-carboniferous limestone formation in Edmondson County, Kentucky, after the Indianapolis meeting of the American Association for the Advancement of Science. After a general description of the cave and history of its inhabitants, it contains a description, with drawings, of all the species of Crustacea and insects which are found in it. The Rev. Samuel Lockwood writes an account of "A Singing *Hesperomys* or Vespermouse," the species known as the jumping-mouse, wood-mouse, and white-footed mouse, with the notes of its song. This number concludes Vol. v. of this admirably-conducted magazine, which we commend to the notice of all interested in the study of natural history.

Journal of Botany for January. A me moir of the late lamented editor of this journal, Dr. Berthold Seemann, commences the new

volume, now conducted by Dr. Trimen, assisted by Mr. J. G. Baker. The original articles are as follows:—"On the Genus *Albizia*, nearly allied to *Acania*," by Baron Ferd. von Mueller; "*The Erysiptæ* of the United States," by Messrs. M. C. Cooke and Peck; a continuation of Mr. J. G. Baker's "Botany of the Lizard Peninsula;" and Lichenographical Notes, by J. A. Martin. Short notes, reviews, and reprints, complete the programme of the number.

THE first article in the *Quarterly Journal of Science* for January is by Captain S. P. Oliver, on "The Dolmen Mounds and Amorpholithic Monuments of Brittany," in which he details the history and analogies of these mounds, classifying them into twelve distinct varieties. The article is apparently not complete. Next follows a short paper on "The Illumination of Beacons and Buoys," detailing the most recent inventions in this direction. The third article is on "Natural and Artificial Flight," detailing M. Marey's investigations on this subject, with numerous illustrative woodcuts. A paper on "The Coal Commissioners' Report" is simply a *résumé* of the evidence brought before the Commission. Mr. Mungo Ponton, on "The Spectroscope: its Imperfections and their Remedy," advocates the construction of an instrument on the diffracting principle, without which the writer maintains that accuracy, certainty, and uniformity of results cannot be attained. The last and longest article in the number is on "Modern Cannon Powder," with two steel plates. A larger proportion than usual of this number is occupied by notices of books, and details of the progress of the physical and mechanical sciences.

THE last published part of the "Memoirs of the Natural History Society of Danzig" ("Schriften der Naturforschenden Gesellschaft in Danzig," New Series, vol. ii., Hft 3 and 4) contains but few papers of general interest, although the special scientific importance of some of them is doubtless very great. Thus a great part of it is occupied by a number of tables giving the results of meteorological observations made in Danzig, with great care and astonishing labour, by M. F. Strehlke, during the years 1841-43, and by a series of tables of refraction for microscopes, by M. E. Kayser. Two other papers of almost purely local interest relate to the chemical composition of the water supplied to Danzig, and to its effects upon lead pipes. The preceding papers occupy more than half the number before us; the remainder all relate to natural history matters. M. C. G. H. Brischke continues his minor observations upon insects, the greater part of his present communication relating to the enemies of the rape-plant and their parasites. The dipterologist will find a new species of *Phytomyza* described under this head. The same author contributes a list of the Rhynchota of the Province of Prussia. The fourth section of M. A. Menge's Prussian Spiders completes the list of zoological contributions. In it the author describes the first two families of his third tribe (the Tubitelæ), ending with *Argyroseta aquatica*, as the 170th species here described by him. M. A. Ohlert's "Lichenological Aphorisms," the only botanical paper, contains some important and interesting observations.

THE following are the most important articles in the *Revue Scientifique*, Nos. 25-32. Prof. Lorain, of Paris, has an interesting article on the report of the Committee of 1870 on the liberty of higher instruction; Mr. Herbert Spencer contributes a paper on General Laws; report of M. Quatrefage's course of lectures on Anthropology at the Museum of Natural History; Helmholtz's address in memory of Prof. Magnus at the Academy of Sciences at Berlin; Herbert Spencer on the Classification of the Sciences, an elaboration of his essay "On the Genesis of Science," published in 1854; Berthelot on the state of bodies in solution; report of Prof. Bernard's course of lectures at the College of France on Experimental Medicine; abstracts of paper read at the Indianapolis Meeting of the American Association for the Advancement of Science; translations of Lockyer's, Maclear's, and Respighi's accounts of the Total Solar Eclipse, together with reports of M. Janssen's observations; an article by Herbert Spencer on the reasons why he dissents from the philosophy of Comte, being a reply to a review in the *Revue des Deux Mondes*; M. Verneuil on Surgical Pathology; report of the committee appointed by the Society of Physicians and Surgeons of the Paris Hospitals to visit the new Hôtel Dieu; M. Alglave on the scientific *réunions* at the Assembly; M. Hebert on the "Tithonic Stage," and the new German school. There are in addition a number of reports of proceedings of foreign societies.

SOCIETIES AND ACADEMIES

LONDON

Royal Institution, February 5.—Sir Frederick Pollock, Bart. vice-president, in the chair. Messrs. Alexander Brodie, John Clegmont, Edward John Gayer, Arthur Edward Griffiths, William Grogan, the Hon. Frederick H. North, Messrs. Samuel Wagstaff Smith, W. Soames, Henry Virtue Tebbs, Burney Yeo, Henry Yool, were elected members. The special thanks of the members were returned for the following donations to "The Fund for the Promotion of Experimental Researches":—"Prof. Tyndall (3rd donation) 30/-, Mr. Arthur Giles Puller (5th donation) 21/-. The presents received since the last meeting were laid on the table, and the thanks of the members returned for the same.

Geologists' Association.—A special general meeting was held on the 2nd February, when a revised code of laws was adopted. Subsequently, at the annual meeting, the report for 1871 was adopted, and the officers for the ensuing year elected. At the ordinary meeting which followed, the Rev. J. Wiltshire, M.A., F.G.S., president, in the chair, a paper was read by the Rev. T. G. Bonney, M.A., F.G.S., tutor of St. John's College, Cambridge, "On the Chloritic marl, or Upper Greensand, of the neighbourhood of Cambridge." The author commenced by a brief sketch of the geology of the Cam valley, and the position of the seam, barely a foot in thickness, which rests upon the eroded surface of the Gault, and is full of green grains and dark nodules, rich in phosphate of lime. He described the matrix as a fine chalky marl, full of foraminifera, and minute fragments of organisms, with a considerable mixture of mud, insoluble in hydrochloric acid. The composition of the green grains (commonly called glauconite) was then discussed, and it was shown that they differed considerably from the typical mineral of that name; he had not satisfied himself that any were casts of foraminifera. After a few words on the phosphatic nodules, and some erratic rocks in the bed, he gave a sketch of the paleontology of the deposit, calling attention to the condition of the various fossil remains, and to the number and size of the pterodactyls and turtles. He then gave his reasons for considering this deposit as formed during the Upper Greensand epoch, but as containing many fossils which had been derived from the Upper Gault by slow denudation. The nodules he considered as mainly of concretionary origin; for they were too pure to be regarded as clay saturated by phosphate. He concluded by sketching out his conception of the physical geography of the East Anglian district in the Neocomian and lower part of the Cretaceous epoch.—Prof. Morris, after some remarks on the value of the paper, spoke of the composition of the green grains, and then traced the range of the deposit, which he agreed with Mr. Bonney in thinking was the formation of a very long period of time.—Mr. Lobley remarked upon the mineralogical and paleontological differences existing between the Cambridge deposit and the chloritic marl of Dorsetshire.—Mr. Bonney, in his reply, having referred to the great scarcity of fossils in the Gault of Cambridge, the Rev. T. Wiltshire stated that the Gault of Kent was in some places devoid of organisms.

Zoological Society, February 6.—Mr. R. Hudson, F.R.S. V.P., in the chair.—A communication was read from Dr. J. S. Bowerbank, F.R.S., containing the first portion of a series of papers, entitled "Contributions to a general History of the Spongiade," in which descriptions were given of several species of *Tethys*, and of *Halispongia choanoides*.—A communication was read from Dr. John Anderson, containing notes on a young living female of *Rhinoceros sumatrensis*, which had been captured in Chittagong, in February 1868, and had been removed to Calcutta on its way to England. These notes were accompanied by a photograph of the animal from life.—A second communication from Dr. Anderson contained notes on *Manouria* and *Scapia*, two supposed genera of Land-Tortoises, which Dr. Anderson showed to be identical with *Testudo emys* of Schlegel and Müller.—Mr. Slater read a paper on Kaup's Cassowary (*Casuarus Kaupii*), of which the Society's collection contained a living specimen. To this was added a list of the other known species of the genus *Casuarus*, and an account of their geographical distribution.—A communication was read from Dr. A. Günther F.R.S., on two specimens of Lizards of the genus *Hydrosaurus*, from the Philippine Islands, for one of which, being hitherto undescribed, Dr. Günther proposed the name *Hydrosaurus nuchalis*.—A second communication from Dr. A. Günther contained the

description of a new genus and species of Characinoïd Fishes from Demerara, proposed to be called *Nannostomus beckfordi*.—A communication was read from Lieutenant Reginald Bevan, of the Revenue Survey Department of India, containing descriptions of two new species of Cyprinoïd Fishes from the Punjab.—Mr. Howard Saunders exhibited specimens of and described a new species of Green Woodpecker from Southern Spain, which he proposed to call *Gecinns sharpii*.

Anthropological Institute, February 5.—Dr. Charnock, vice-president, in the chair. W. J. Jeaffreson, M.A., was elected a member.—Lieut. Col. G. G. Francis exhibited a series of flint, stone, and bone implements and human bones from Paviland, Gower.—Mr. George Harris, vice-president, read a paper "On the hereditary transmission of endowments and qualities of various kinds." Of the actual transmission of qualities no doubt could be entertained. Many thought they were mainly derived from the mother, and in some instances they were inherited from the grandparents. That was often observed in cases of disease. Endowments did not, however, always directly descend, but were transmitted in various ways, such as in the descent of particular talents. In other cases it was modified in the transmission; occasionally the various qualities of both parents seemed to be divided among the different members of the family. That was observable in the breeding of animals. Physical qualities were also transmitted in the same way, and artificial acquirements had been considered transmissible. The most extraordinary instances were related of the existence of complete continuity, both mental and moral, between the parents and the children. The author considered the subject to be one of deep interest, and suggestive of various theories, and respecting which the observations of each might add to the common stock of knowledge.—A paper on "the Wallons," by Dr. Charnock and Dr. Carter Blake, was then read. The Wallons were descendants of the old Gallic Belge who held their ground in the Ardennes, when Gaul was overrun by the Germans. The Wallons were tall, somewhat slender, raw-boned, tough, rough, and hardy, and made excellent soldiers. Their hair was dark, eyes fiery, dark-brown, or blue, and deep sunk. The ordinary Wallons stood in a similar relation to Belgium to what the Irish peasant did to the Sassenach. They were poor, jovial, good-natured, superstitious, chaste, hospitable, quarrelsome, violent, and generous, like the Irish. They were poetical, rich in song, and fond of the dance. They surpassed the Flemish in adroitness, activity, and skill, and the French in earnestness, perseverance, and diligence. As evidence of their peculiar character, a Wallon would drag a pig from Namur to Ghent, or even to Bruges, to gain a few sous more than he could in his own district. Some of the most eminent of the modern statesmen of Belgium were of Wallon descent. Notwithstanding these general remarks, a special mental and moral character might be predicated of the Wallons of each district. The paper concluded with copious remarks on the language of the Wallons, together with their proverbs.

Society of Biblical Archaeology, February 6.—Dr. Birch, president, in the chair.—The following gentlemen were duly proposed as members of the society:—Mr. T. H. Christy, Mr. James Collins, Mr. George C. Hale, Rev. Prof. Mahaffey. An important communication was received from M. Clermont Ganneau, on an "Inscription in Hebrew or Ancient Phœnician Characters of the time of the Kings of Judah, discovered at Siloam-el-Fokani, near Jerusalem." In this paper M. Ganneau related the discovery of two incised tablets, executed on the wall of a ruined rock-cut chamber or scællum, near to the house of the Sheikh of Siloam. The inscriptions were in the old Archaic character, now familiar to the archaeological world in the famous Moabite Stone. Some Christian hermit had, about the fourth century of our era, wilfully mutilated part of the writing, but enough still remained to attest its extreme value as a paleographic record. Portions of the first four lines of the first tablet the learned savant believed to contain the name of the divinity Baal, and to denote a votive dedication to him by a functionary, name illegible, after the period of the later Kings of Judah. The author inclined to think that the cave had been originally dedicated to Baal at a still earlier period, probably by one of Solomon's Moabitish wives, and that it was afterwards added to and finished in a subsequent reign. M. Ganneau promised, in conclusion, shortly to lay before the society a more perfect examination and conjectural restoration of the inscriptions on both

tablets, and expressed a hope that the records in question would prove not inferior in importance to any other, as being themselves the oldest, or nearly the oldest, positively Hebrew inscriptions in existence.

Mathematical Society, February 8.—Prof. Cayley, vice-president, in the chair. The chairman mentioned that the president had made inquiries at the Home Office as to the mode of procedure requisite for obtaining a charter for the society, and that the matter would come on for consideration at the next subsequent meeting (March 14) when members would have an opportunity of stating their views upon the desirability of incorporation.—Mr. J. W. L. Glaisher was elected a member of the society.—Mr. Cotterill gave an account of his paper "On an Algebraical Form, and the geometry of its dual connection with a polygon, plane, or spherical." The chairman, Dr. Hirst, and Prof. Clifford took part in a discussion on the paper.

Entomological Society, February 5.—Prof. Westwood, president, in the chair.—Mr. McLachlan brought before the notice of the meeting an illustration of the manner in which the increase of plant-lice is checked by Hymenopterous parasites; a family of aphides collected round a poplar twig exhibited had been utterly destroyed by these parasites, there remaining only the inflated empty skins much resembling the egg of some large insect, and each with a circular hole whence the parasite had emerged.—Mr. Druce exhibited a selection from a large collection of butterflies formed in Costa Rica by Dr. Van Patten. It included about fifty new species and one new genus. Amongst the more striking forms were four new species of *Papilio*, three of *Morpho*, three or four of *Leptalis*, &c.—Prof. Westwood exhibited drawings and specimens of various interesting species of *Acarnia*, including forms new to Britain. One of these was allied to the poisonous *Argas persicus*, and had been found in the crypt of Canterbury Cathedral. Mr. Bond had also seen examples found in a church on a gentleman's coat after two young bats had fallen upon him from the roof. Another pertained to the genus *Trogulus*, and had been found in Dorsetshire.—Major Parry read a paper on new species of *Leucanoid Coleoptera*, which was followed by others by Prof. Westwood and M. Snellen van Sollenhoven, on insects of the same family.

EDINBURGH

Royal Physical Society, January 25.—Dr. Robert Brown, president, in the chair.—Prof. Turner exhibited a large specimen of the electrical eel (*Gymnotus electricus*) of South America, which he had received a few weeks ago from Dr. Ridpath, surgeon, West India Mail Steam Packet Service. He described the arrangement of the electrical organs, and compared them with the corresponding organs in *Torpedo*, *Malapterurus*, and *Almonyrus*, and in the tail of the common skate. Dr. T. Strehill Wright made some remarks on the relation of these curious organs to various electrical apparatus. The organs of the electrical fishes were not properly batteries, but were probably condensing apparatus. Some time ago he made an artificial electrical eel, and with it he had performed all the experiments Prof. Faraday had done with the electrical eel itself, which he would exhibit and explain to the society. He gave a sketch on the board of condensing voltaic apparatus, which was probably analogous to that of the electrical fishes.—Various species of Pedunculated Cirripedes of Barnacles were exhibited from Shetland, Cornwall, the Black Sea, &c., by Mr. C. W. Peach. In October last Mr. Gatherer, of Lerwick, sent him a fine colony of *Lepas fascicularis* which had been taken floating off Kirkallister lighthouse by a gentleman fishing, and who saw a great many similar masses floating past his boat. They are each attached to a bulb like mass, and are in various stages of growth. About ten are left, some having fallen off. When very young they are attached by a short peduncle to feathers, cork, cinders, and seaweeds, or any other floating object. As they increase in size they form a bulb on the foot-stalk. This in time becomes so large that it falls off, and thus the animal is buoyed up with it—in fact, "paddles its own canoe." When thus afloat the animals multiply, and the bulb is enlarged also. It is far from rare, and found in all seas. In Cornwall, after long-continued south-west winds, it is thrown ashore by thousands.—Remarks on the Diamond Fields of South Africa," by Mr. Andrew Taylor.

DUBLIN

Royal Geological Society of Ireland, January 10.—Dr. W. Frazer in the chair. Prof. E. Hull, F.R.S., read some notes on the Marble of Carrara.—Prof. Macalister read

notes of some further "Researches on Conchospirals." He pointed out the geometrical properties of the logarithmic spirals of Mollusca, the special form of spiral in Ammonites, and the methods of deducing the individual specific parameters from (a) tangential measurements, (b) horizontal sections, and (c) vertical sections.—The Chairman exhibited a human skull from Swan River, Australia, encrusted with shells and much acted on by water.

PARIS

Academy of Sciences, February 5.—M. Serret presented a note by M. A. Mannheim, containing generalisations of Meunier's theorem.—M. H. Resal presented a memoir on the mechanical effects of the American hammer.—A memoir was read by M. E. Duclaux on the laws of the flow of liquids in capillary spaces.—Mr. P. Blaserna presented a note on the solar atmosphere, in which he claims to have arrived at the same conclusions with M. Janssen, from his observations during the eclipse of December 22, 1870.—M. Renou replied to the observations made by M. Delaunay with regard to the Meteorological Annual of the Paris Observatory at the last meeting of the Society, and M. Le Verrier suggested the appointment of a committee to revise the meteorological observations presented to the Academy during the last century, and to bring out an authentic edition of them.—Communications, descriptive of the aurora observed in France and elsewhere on the evening of February 4, from MM. Frou, Salicis, Laussedat, and Chapelas, were read, as also an extract from a letter from M. Cornu to M. Fizeau upon the spectrum of the same aurora. The most important result obtained by the last-mentioned author was the determination of the existence of a yellowish-green band coinciding with that previously observed by Angström in 1867-68.—M. Prazmowski also presented a note on the spectral investigation of the aurora of Feb. 4. He described a green band about E of Fraunhofer (seemingly identical with that observed by M. Cornu), a red band near C, and two more very faint bands in the blue and violet, near F and G.—M. Bobierre communicated some chemical investigations on the Landes of Brittany, in which he noticed especially the constituents of the ashes of plants grown on those soils. They are chiefly remarkable for the great quantity of silica contained in them and their poverty in alkaline salts.—M. Cahours presented a note by M. G. Chancel, on the contraction of solutions of cane sugar at the moment of inversion, and on a new saccharimetric process. The author described the method employed by him, and stated that a solution of cane sugar, after inversion, has undergone an appreciable diminution of volume, which increases in proportion to the amount of sugar in solution. Upon this property he proposes to found a new method of saccharimetry.—M. Sacc presented an analysis of the linseed oil referred to in a recent memoir read to the Academy.—M. Dupuy de Lome read two long and exceedingly interesting papers upon the construction of a screw aeroplane invented by him, and on the results of a trial trip made with it. The machine consists of an oblong balloon, with a boat-shaped car; the author describes it as presenting great stability. The propeller worked by eight men moved the balloon through the air with a velocity of 2.82 metres per second, or 10½ kilometres (about 6½ miles) per hour, so that a certain amount of power over the movements of the machine was obtained.—The warm discussion upon heterogeny and the nature of fermentation was continued at this meeting by a second communication on the latter subject by M. Fremy, who denies that the experiments of M. Pasteur have anything to do with fermentation. He also declared that his theory has nothing in common with that of Liebig, with which it was identified by M. Wurtz. The paper contained accounts of experiments made with malt, yeast, milk, and grape-wort, and upon the decomposition of organic bodies by the action of moulds.—MM. Dumas and Balard made some remarks on this communication, and M. V. Meunier presented a note in which he stated that organic bodies do frequently make their appearance in solutions treated after M. Pasteur's method, so that, he thought, the results obtained by that gentleman are not conclusive.—M. de Quatrefages presented a note by M. E. T. Haüy describing the occurrence of brachycephalous negroes among the Camnans on the shores of the Fernand-Vaz River in Western Africa.—M. Milne-Edwards described a self-regulating gas-heating apparatus in use in the zoological laboratory of the Museum; and M. Sichel *in situ* forwarded the description of a new ophthalmoscope for simultaneous observations by two persons.

BOOKS RECEIVED

ENGLISH.—A Treatise on Attractions, Laplace's Functions, and the Figure of the Earth, 4th edition: J. H. Pratt (Macmillan and Co.)—Science and Humanity: Noah Potter (Hodder and Stoughton).—Solid Geometry and Conic Sections: J. M. Wilson (Macmillan and Co.)—Report by the Committee on Intemperance, for the Lower House of Convocation: (Jas. Clarke and Co.)—Our National Resources and how they are reached: W. Hoyle (Simpkin and Marshall).—Consumption, and the Breath re-breathed: Dr. H. M'Cormac (Longmans).

FOREIGN.—Bulletin de la Société Impériale des Naturalistes de Moscou, 1871, Nos. 1 and 2.

DIARY

THURSDAY, FEBRUARY 15.

ROYAL SOCIETY, at 8.30.—On the Induction of Electric Currents in an Infinite Plane Conducting Sheet: Prof. Clerk Maxwell, F.R.S.—On some Derivatives of Uramido-benzoic Acid: J. P. Griess, F.R.S.

SOCIETY OF ANTIQUARIES, at 8.30.

LINNEAN SOCIETY, at 8.—On a Chinese Artichoke Gall: A. Müller, F.L.S.—On the Habits, Structure, &c., of the Three-banded Armadillo: Dr. J. Murie, F.L.S.—Comparative Geographical Distribution of Butterflies and Birds: W. F. Kirby.

CHEMICAL SOCIETY, at 8.

FRIDAY, FEBRUARY 16.

ROYAL INSTITUTION, at 3.—On the Crystallisation of Silver and other Metals: Dr. Gladstone, F.R.S.

GEOLOGICAL SOCIETY, at 1.—Anniversary Meeting.

SATURDAY, FEBRUARY 17.

ROYAL INSTITUTION, at 3.—On the Theatre in Shakespeare's Time: Wm. B. Donne.

SUNDAY, FEBRUARY 18.

SUNDAY LECTURE SOCIETY, at 4.—On the Human Hand, as Illustrating the Scheme of Creation: Lawson Tait.

MONDAY, FEBRUARY 19.

ENTOMOLOGICAL SOCIETY, at 7.

ANTHROPOLOGICAL INSTITUTE, at 8.—Structures on Darwinism: H. H. Howorth—Race Characteristics as related to Civilisation: J. Gould Avery.

LONDON INSTITUTION, at 4.—Elementary Chemistry: Prof. Odling, F.R.S.

TUESDAY, FEBRUARY 20.

ROYAL INSTITUTION, at 3.—On the Circulatory and Nervous Systems: Dr. Rutledge.

ZOOLOGICAL SOCIETY, at 9.—Notes upon the Anatomy of the young Hippopotamus, as observed in the specimen which died in the Society's Gardens on the 10th January, 1872: J. H. Clark.—Contributions to a General History of the Spongidae. Part II.—Dr. J. S. Lowerbank.—On the Spiders of Palestine and Syria: containing a general list with descriptions of numerous new species and characters of two new genera: Rev. O. P. Cambridge.

STATISTICAL SOCIETY, at 7.45.—On Prison Discipline and Statistics in Lower Bengal: Dr. Mouat.

WEDNESDAY, FEBRUARY 21.

GEOLOGICAL SOCIETY, at 8.—Migrations of the Graptolites: Prof. H. Alleyne Nicholson, F.G.S.—How the Parallel Roads of Glen Roy were Formed: Prof. James Nicol, F.G.S.—Notes on Atolls or Lagoon-islands: S. J. Whitnell.

SOCIETY OF ARTS, at 8.—On Prison Labour, as an Instrument of Punishment, Profit, and Reformation: F. J. Mouat.

ROYAL SOCIETY OF LITERATURE, at 8.30.—On Results of recent Excavations in Rome: Mr. Vaux.

METEOROLOGICAL SOCIETY, at 7.

THURSDAY, FEBRUARY 22.

ROYAL SOCIETY, at 8.30.

ROYAL INSTITUTION, at 3.—On the Chemistry of Alkalies and Alkali Manufacture: Prof. Odling, F.R.S.

SOCIETY OF ANTIQUARIES, 8.30.

THURSDAY, FEBRUARY 22, 1872

THE ROCK THERMOMETERS AT THE ROYAL OBSERVATORY, EDINBURGH

THE whole of the observations made with these instruments (reading to hundredths of a degree Fahrenheit) from 1837 to 1869 having been reduced on a uniform plan, and found to exhibit some well-marked supra-annual cycles, a paper on the subject and on their relations to the sun-spot cycles of similar period but diverse shape was sent in to the Royal Society, London, on March 2, 1870.

Since then two eminent astronomers, one of them being Mr. Stone, the newly appointed Astronomer Royal at the Cape of Good Hope, and the other Mr. Cleveland Abbe, Director of the Cincinnati Observatory, have published somewhat similar deductions touching atmospheric temperatures in reference to sun-spots; Mr. Stone basing on thirty years of South African temperature observed by his indefatigable predecessor Sir T. Maclear; and Mr. Abbe on sixty years' temperature observed on the elevated station of Hohenpeissenberg near Munich, under the superintendence of Dr. Lamont, the Bavarian Astronomer Royal; both parties, equally with myself, using the same famous series of observations of sun-spots, as made by M. Schwabe, and discussed both by Prof. Wolf and Prof. Balfour Stewart. More recently still a Canadian writer, employing the returns of the Toronto Observatory for many years past, considers that he has established a connection between the amount of annual rainfall there and the sun-spots; and of these again with the periods and dates of several interlacing streams of circum-solar meteors. And within the last few days the Radcliffe Astronomer announces in his report for 1871 that the mean azimuthal direction of the wind at Oxford, rigorously computed from automatic records during the last eight years, varies year by year through a range of 58° on the whole, between *maximum* and *minimum* of visible sun-spots; the tendency of the wind to a westward direction increasing with the number of spots, and with such west wind, it is to be presumed, the amount of rain also.

These results touch closely on the hopes of physicists to render meteorology more of an exact science by getting at its cosmical relations, but they also touch equally close on another point where the highest science is at present completely dumb, although too it is the very point where the utmost amount of benefit might be conferred on the largest numbers of the people, viz., some approximate indications of the character of the seasons for a year or two beforehand; or indeed, very much as I did make a first attempt, for the two winters of 1870-71 and 1871-72, in the paper presented to the Royal Society in the spring of 1870.

How intimately the well-being of the poor generally, as well as of the agricultural classes, depends on those characteristics of weather which no scientific society can at present foretell, and no Ministry prevent in their destructive effects to the national revenue when they do come, the following letter may serve as a better example than anything that I could prepare on theory alone:—

"Webb's Green, Hales Owen, June 12, 1871

"To C. Piazzi Smyth, Esq., Edinburgh

(Copy)

"Sir,—I am a reader of *Chambers' Journal* and a farmer of some 600 acres. In the publication of Messrs. Chambers I read that you had expressed an opinion from certain observations you had made that the late winter would be very severe. For the general run of weather prophets I have very little respect; but every respect for opinions that are the result of scientific induction.

"Consequently I conducted my farming operations with due regard to your prognostication, and as the result has been a profit to me, I write to thank you. Gratitude has been defined as 'a lively sense of favours to come,' and from that view and in consideration of the present weather if you could give me your opinion of the weather that you think likely to prevail for some time to come I should feel much obliged.

"I have not troubled you with this epistle entirely from a selfish point of view, for besides being a farmer I am unfortunately an employer of a very underpaid class of workmen, hand rail makers.

"Now that stocks of wheat are exhausted, meat is a luxury to which railers cannot aspire; and if the season continues ungenial, before the harvest of 1872 there may be absolute scarcity of bread. I want to get up a fund for emigration, but if you could give me any information as to the probabilities of season that would dispel my gloomy anticipations for next winter, I should rejoice.—I am, &c., &c. (Signed) "THOMAS BISSELL"

But I have so little desire to incur responsibility for any weather predictions that I have gladly availed myself of the opportunity of the publication of the 13th volume of the Edinburgh Astronomical Observations to lay before the public by means of the several Plates 11 to 15 inclusive a complete graphical representation of the whole series of Edinburgh rock-thermometer observations, and on which I will merely venture the following explanatory remarks:—

1. The most striking and positive feature of the whole series of observations is the great heat-wave which occurs every eleven years and a fraction, and nearly coincident with the beginning of the *increase* of each sun-spot cycle of the same eleven-year duration. The last observed occurrences of such heat-wave, which is very short lived and of a totally different *shape* from the sun-spot curve, were in 1834-8, 1846-4, 1857-8, and 1868-8, whence, allowing for the greater uncertainty in the earlier observation, we may expect the next occurrence of the phenomenon in or about 1880-0.

2. The next largest feature is the extreme cold close on either side of the great heat-wave; this phenomenon is not quite so certain as the heat-wave, partly on account of the excessive depth and duration of the particular cold wave which followed the hot season of 1834-8. That exceedingly cold period, lasting as it did through the several successive years 1836, 37, and 38, was, however, apparently a rare consequence of an eleven year minimum occurring simultaneously with the minimum of a much longer cycle of some forty or more years, and which has not returned within itself since our observations began. Depending therefore chiefly on our later observed eleven-year periods, or from 1846-4 to 1857-8, and from the latter up to 1868-8, we may perhaps be justified in concluding that the minimum temperature of the present cold wave was reached in 1871-1, and that the next similar cold wave will occur in 1878-8.

3. Between the dates of these two cold waves there are located, according to all the cycles observed, even including that earlier one otherwise exceptional, three moderate and nearly equidistant heat-waves, with their two intervening and very moderate cold waves, but their characters are quite unimportant as compared with what is alluded to under heads 1 and 2; and with regard to all the waves, it may be just to state that there has been in observation more uniformity, and will be therefore in prediction more certainty for their dates than for their intensities.

February 1872

DARWIN'S ORIGIN OF SPECIES

The Origin of Species by means of Natural Selection; or the Preservation of Favoured Races in the Struggle for Life. By Charles Darwin, M.A., F.R.S. Sixth edition, with additions and corrections. (London: J. Murray, 1872.)

FEW are the writers, scientific or otherwise, who can afford, in every successive edition of their works, to place side by side the passages which they have seen reason to alter, from a change of view or any other cause. And yet to this point we find especial attention called in each succeeding edition of Mr. Darwin's "Origin of Species." And herein lies the true humility of the man of science. Science is often charged with being arrogant. But the true student of Nature cannot be otherwise than humble-minded. That man is unworthy of the name of a man of science who, whatever may be his special branch of study, has not materially altered his views on some important points within the last twelve years.* The means at our command for obtaining correct views of the laws which govern Nature are ever increasing, and if we only

Let knowledge grow from more to more,
this can but cause that

More of reverence in us dwell,
reverence for the eternal constancy of Nature's laws, with respect to which we even yet know so little. But a false pride more often tempts men to conceal than to avow their change of opinion. Mr. Darwin carries the contrary practice perhaps to an excess. But such a course necessarily disarms criticism of its sting; and if the learner sometimes ventures to point out wherein he differs from the master's conclusions, it is only in the hope that the interchange of opinion may lead to a removal of the difficulties which prevent a complete accord of thought.

The sixth edition of the "Origin of Species" is considerably smaller than its predecessors; but this does not arise from any diminution of matter, but from the use of smaller type. There has been, in fact, considerable addition, and our province will be simply to call attention to those points in which previous editions have been amended or amplified. Already, in the fifth edition, Mr. Darwin had stated that the able criticism of his work which appeared in the *North British Review* had induced him to modify his views with regard to the frequency of the occurrence of characters which are not useful to the

individual; we find now, on some other points, a similar modification of opinion.

It has always seemed to us that one of the weakest parts of Mr. Darwin's statement of the theory of natural selection is the emphasis with which he asserts that single instances of departure from the law would prove the theory to be unsound. In the present edition, speaking of the rattle of the rattlesnake—the only effect of which has been stated to be to direct to the snake the attention of its enemies—he goes out of the way to repeat that "if it could be proved that any part of the structure of any one species had been formed for the exclusive good of another species, it would annihilate his theory." Why it would annihilate his theory, we must confess we are unable to understand; since Mr. Darwin repeats in this edition even more emphatically than in previous ones that "he is convinced that natural selection has been the main, but not the exclusive, means of modification of species." Since then other causes have been at work to cause the evolution of species, why may not some of these causes be able to produce parts beneficial to the race rather than to the species? In the special case, however, under consideration, the rattle of the rattlesnake, an American naturalist comes to the rescue of the Darwinian theory. Mr. Darwin was probably not aware at the time of writing that Prof. Shaler had stated his belief, from the result of observation, that the rattlesnake's rattle is actually beneficial to it, its object being to imitate the sound of the cicada or other insect which forms the food of many birds, thus attracting them within its power, and accounting for the apparent "fascination" of its prey, which must now be consigned to the limbo of travellers' tales.

The greater part of the additional matter in this edition is naturally devoted to a reply to the objections urged in Mr. Mivart's "Genesis of Species." In replying to Mr. Mivart's objection to the theory that "mimicry" has resulted by the process of natural selection, on the ground that the early stages of resemblance would have no useful tendency, the following sentences appear to us to be open to objection, or to be wanting in clearness:—"But in all the foregoing cases the insects, in their original state, no doubt presented some rude and accidental resemblance to an object commonly found in the stations frequented by them." "Assuming that an insect originally happened to resemble in some degree a dead twig or a decayed leaf." What is meant by the "original state" of an insect? Every insect-form must have been evolved from some previously existing simpler form by a gradual process, and the "rude or accidental resemblance" must be due to the operation of the same causes that produced the finished likeness. We must acknowledge that Mr. Darwin appears to us to fail to grapple with the difficulty in the way of the application of his theory, that either the early stages of the "mimicry" are useless, or that the exact reproduction of figure and pattern in the "mimicking" insect is a mere freak of nature. Mr. Darwin states his belief that "the sight of birds is probably sharper than ours," which would tell heavily against the utility of the first approaches towards resemblance; Mr. Wallace, if we recollect rightly, has expressed a contrary opinion.

Mr. Mivart's objection with regard to the curious fact

* The first edition of the "Origin of Species" was published in 1859.

that in the Pleuronectidae, or Flat-fish, the eyes are opposite in the young state, and afterwards become placed both on the upper side of the head—that this change must have taken place suddenly, since any small approach to it would not be useful—is met by an ingenious argument, previously advanced by Malm. It is stated that “the Pleuronectidae, whilst still very young and still symmetrical, with their eyes standing on opposite sides of the head, cannot long retain a vertical position, owing to the excessive depth of their bodies, the small size of their lateral fins, and to their being destitute of a swim-bladder. Hence, soon growing tired, they fall to the bottom on one side. While thus at rest, they often twist, as Malm observed, the lower eye upwards to see above them, and they do this so vigorously that the eye is pressed hard against the upper part of the orbit. The forehead between the eyes consequently becomes, as could be plainly seen, temporarily contracted in breadth. On one occasion Malm saw a young fish raise and depress the lower eye through an angular distance of about 70° .”

The objections urged by Nägeli in his “Begriff und Entstehung der naturhistorischen Art,” with respect to plants, that the families of plants differ chiefly from each other in morphological characters, which appear to be quite unimportant to the welfare of the species, are combated on the ground that we ought to be exceedingly cautious in pretending to decide what structures now are or have formerly been of use to each species. While admitting that in earlier editions he underrated the frequency and importance of modifications due to spontaneous variability, Mr. Darwin points out that many peculiarities of structure, lately supposed to be simply morphological, are now known to be intimately connected with facilities for fertilisation.

On the whole it seems to us that each succeeding edition of the “Origin of Species” lessens the distance between Mr. Darwin and those who believe that the influence of natural selection, though a *vera causa*, has been overrated as an element in the evolution of species. If it is admitted that important modifications are due to “spontaneous variability,” that natural selection is not the exclusive means of modification, Darwinians and non-Darwinians have equally before them the problem to discover what these other laws are which are co-efficient in the production of new species, and what part each of these plays in producing the final result. Until this is accomplished we can hardly consider the great problem of the Origin of Species as solved. Towards the solution of it, however, the labours of Mr. Darwin will ever be held as having contributed a larger share than those of any other naturalist. When we look at the title-page, and see that a work which has produced a greater revolution in the scientific thought of the day than any published in this country since Newton’s “Principia” is yet only in its eleventh thousand, and reflect that, although this is not a small sale for a scientific work, yet books which contain the germ of new thought, and contribute not one iota to our sum of knowledge, have sold their hundreds of thousands, we cannot but think that in the coming age, when the people will really care about science, our descendants will regard this unworthy fact in the light that we do the unpopularity of the writings of Milton and Goldsmith during their lifetime.

We must not omit to mention a very useful addition, for the unscientific reader, made to this edition, in the shape of a glossary of the principal scientific terms used, prepared by Mr. W. S. Dallas.

ALFRED W. BENNETT

MAXWELL ON HEAT

Theory of Heat. By J. Clerk Maxwell, M.A., LL.D. (London : Longmans and Co. 1872.)

IT is very seldom that we meet with a book so instructive and delightful as Prof. Maxwell’s “Theory of Heat.” It has peculiar claims upon the student of Physics, inasmuch as it supplies a want which has been long and widely felt. The point of view is undoubtedly a new one, and to enable our readers to perceive the value of the book, we ought to make a few remarks upon the kinds of text-books that we have hitherto had. In these books the aim has been to inform the student’s mind, and the fault to inform it too minutely and too exclusively. They have been of two classes—elementary books, in which the information is given in a popular manner, and advanced books, through the pages of which mathematical formulæ are very liberally interspersed.

In reading such a book the strength of the student’s mind is devoted to one or at most two objects. If the book be elementary, he is bent upon acquiring a good knowledge of the facts, along with a knowledge, more or less complete, of the experimental methods by which these facts have been obtained. If, on the other hand, the book be an advanced one, his strength is devoted to grappling with and overcoming its analytical difficulties. But after he has studied both classes of text-books, he rises from their perusal with the belief that there is something wanting before he can have a thorough grasp of the subject, and a clear view of its truth and beauty. He has followed the experimenter only too zealously into his elaborate and accurate calculations, or it may be the mathematician into his profound investigations, and he now begins to realise the truth of the poet’s saying—

He who hath watched, not shared, the strife
Knows how the day hath gone,

and to sigh for some elevated spot from which he may obtain a clear view of the whole field. He hears vague rumours that the caloric battalions and their allies the corpuscular forces, have lost the day, but he wishes to see their discomfiture more completely with his own eyes.

Such a point of view is afforded by Prof. Maxwell. He has—wisely, we think—confined himself to this one object, to give the student a clear logical view of the whole subject; nor has he broken the unity of his treatment by going into details, whether experimental or mathematical. Every true student of physics should read this book, and he will unquestionably find it a most delightful study. He will, we venture to say, rise from its perusal with a much truer and wider conception of the science of heat; and if he then wants more detailed information upon any branch, he may consult one of the ordinary text-books. Another beauty of the book is the accuracy and completeness of its historical notes. The author has successfully combined the part of historian and that of logician, and has given us very many valuable references to original memoirs, in which we may see for

ourselves the first germs of the various developments. The only thing wanting in this respect is an index, into which the various facts and names of the book might have been collected with much advantage to the reader.

Another point of interest in the book is the prominence given to the graphical method of representing truth. The Isothermal and Adiabatic curves are largely dwelt upon, and their usefulness in leading us to detect new properties of bodies is well pointed out. We are glad to think that the importance of such graphical representations is becoming well recognised in many departments of science. Even in pure mathematics, if we have occasion to calculate a series of numerical values from a formula, by plotting them upon curve-paper we shall discover at once by the eye if we have made a mistake in our calculation. In like manner, if we plot the result of a series of careful experiments after the manner of Regnault and others, we shall probably be able to determine from the appearance of the curve whether or not we may trust to the accuracy of our determinations.

Finally, by a series of lines similar to those exhibited by Prof. Maxwell, we come to see with great ease the relation that exists between the various properties of bodies; for instance, we see at once and as a direct consequence of the definition, that the ratio between the two specific heats is the same as that between the two elasticities.

We cannot close this review without remarking upon the good English in which this excellent book is written; and this, we trust, will go far to convince the scientific public that the most profound and original treatment of physics is not inconsistent with purity of language.

B. STEWART

OUR BOOK SHELF

Queen Charlotte Islands: A Narrative of Discovery and Adventure in the North Pacific. By Francis Poole, C.E. Edited by John W. Lyndon. (London: Hurst and Blackett, 1872.)

MR. POOLE enjoys the distinction of being the only educated Englishman who has ever lived on Queen Charlotte Islands, where he spent two years in an endeavour to develop the mineral resources of the country. The volume therefore necessarily possesses the interest attaching to a narrative of a residence in an almost unknown country. We miss, however, those touches which add so much to the charm of books of travel, which indicate that the writer has visited many men and many cities, and is capable of contrasting the natural products or the habits of the people of one part of the world with those of another. The attraction for the author to these islands was the presence of copper, to work which a company was formed in 1862. There can be little doubt that copper-veins, and probably other minerals, do exist in the islands in quantities that would amply repay the investment of labour and capital in their working. The climate appears to be equable and agreeable, the harbours are magnificent, and the soil is rich and productive, so that we may hope that at some future time Queen Charlotte Islands will become a valuable dependency of the British Crown. If Mr. Poole's volume succeeds in drawing to their capabilities the attention of those who are competent to develop their resources, it will have performed good service.

Hints and Facts on the Origin of Man, and of his Intellectual Faculties. By Pius Melia, D.D. (London: Longmans and Co., 1872.)

THE writer of this little book states in his preface that "he has brought together systems, facts, statements, and

reasons, taken from all available sources, with the view of elucidating several important truths about man, which are at the present day either called in question or absolutely denied." The extent to which he has consulted, or the accuracy with which he has quoted from, original sources, we gathered from the fact that he entirely passes over, as unworthy of notice, the systems of Goethe and Oken, and from the statement that the "Philosophie Zoologique" of G. B. Lamarck (*sic*) was published in 1830.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

A Zoological Station at Torquay

THE article on "The Formation of Zoological Stations," by Anton Dohrn, which appeared in NATURE of the 8th inst., was read at the meeting of the Torquay Natural History Society on the 14th inst., and was the subject of an animated conversation. I am happy to add that the scheme met the warm approval of the members, and that if a station be established at Torquay, the cordial co-operation of the society may certainly be reckoned on.

W. PENGELLY, Hon. Sec.

Museum, Torquay, Feb. 17

The Chicago Observatory

A LETTER, signed by one of the Professors of the University of Chicago, commenting on the impoverished state of the Chicago Observatory since the great fire in that city, having had an extensive circulation through the Press, I have to request the favour of the insertion in your columns of the following statement on the subject, just received by the Secretary of the Royal Astronomical Society from the Director of the University, Prof. T. H. Safford.

EDWIN DUNKIN,

Hon. Sec. to the Royal Astronomical Society

Royal Observatory, Greenwich, February 22

"Dearborn Observatory, Chicago, Jan. 29, 1872.

"DEAR SIR,—As the enclosed article from the London *Daily News* (see also London *Times* of January 9) might convey the impression that the Observatory is to be closed, permit me to state exactly the facts.

"The Observatory—whose funds are separate from those of the University—has, during the few years of its existence, accumulated a large stock (perhaps too large) of unpublished and only partially discussed observations, especially upon stars between 35° and 40° of declination, in connection with the German Astronomical Society, on Argelander's plan. A few months before the fire arrangements had been in progress by which it would gradually acquire the means to discuss and publish these observations, but these arrangements have been interrupted.

"So far, then, as the City of Chicago is concerned, nothing further is to be expected for the present, and, perhaps, the coming year; but as business has revived, it is expected that the difficulty of providing means will not be permanent.

"For the present it is necessary for me to give a portion of my time to geodetic and geographic-astronomical work for the United States engineers, who are conducting large operations in the central portion of the country; and the publication of our observations will be in consequence delayed.

"It is but fit that I should here acknowledge the indebtedness of the Observatory to the Hon. J. Young Scammon, at whose sole expense the Dearborn Tower and the Meridian Circle Room were built, and upon whom the support of the Institution has mainly depended.

"Our thanks are especially due to those scientific friends who have so kindly given their works. Were it not for the Greenwich and other star-catalogues received by past donations, I should have found myself in no condition to accomplish the work which I am now doing for support.

"T. H. SAFFORD,

"Director of Dearborn Observatory
"To the Secretary of the Royal Astronomical Society."

Composition of Vibrations

WHILE holding one of König's large polished tuning-forks in my hand, I happened to give it a swaying movement on the plane on which its vibrations were being performed, and immediately noticed that the space through which the fork swung was occupied by a series of bright straight lines arranged in a fan-like form. The lines spread out, or drew together, as the rate of movement impressed on the fork increased or diminished. The case was clearly one of composition of vibrations, the bright lines being merely the edges of the prongs seen in positions of instantaneous rest, where the proper motion of a prong was equal and opposite to that communicated to it by the hand.

By taking forks of different pitch, and causing them to swing with equal velocities, the dependence of pitch on the number of vibrations performed in a given time was easily exhibited.

In case this simple observation has not yet been made or described I ask its insertion in NATURE.

Trinity College, Cambridge

SEDLAY TAYLOR

Eclipse Photography

MR. J. BOESINGER, in the last number of NATURE, expresses his surprise at the ignorance of the photographers attached to the late expeditions, and favours them with hints, observations, and instructions still more surprising. Because he cannot see their reasons for employing equatorial stands, plates in separate frames, and long exposures, he concludes these were unnecessary; and affirms "there must have been a great want of balance in their chemicals." No doubt there is a want of balance somewhere, and I diffidently submit the probability that Mr. Boesinger has lost his.

I would briefly state to those few of your readers who may have been misled by this correspondent, that equatorial stands driven by clock-work are absolutely necessary in the production of the best results, either by short or long exposure of photographic plates; a picture "not perfectly sharp but valuable as a memorial," was what Mr. Boesinger aimed at (and I sincerely hope he obtained it), but the expeditions had higher aims and greater expectations. Single large plates were exposed separately, that should a corona extending many degrees be actinically present, it might find ample room to put in an appearance; in such a case had "repeating backs" been used to give many pictures on one plate, there would have been great danger from the corona of one picture over-lapping that of another, to the ruin of all. Comparatively long exposures were found necessary to secure impression from the faint extremities of the rays.

HENRY DAVIS

Tidal Friction according to Thomson and Tait

I AM so afraid that this letter will convict me of hopeless stupidity that I conceal my name. For I am going to confess that I do not understand, and even feel inclined to dispute, the reasoning of Thomson and Tait, on pp. 191-194 in their great work, respecting the effect of tidal friction on the motion of the earth and moon. It will be a convenience to your readers if I quote the passage at full length:—

"Let us suppose the moon to be a uniform spherical body. The mutual action and reaction of gravitation between her mass and the earth's will be equivalent to a single force in some line through her centre, and must be such as to impede the earth's rotation as long as this is performed in a shorter period than the moon's motion round the earth. It must therefore lie in some such direction as the line MQ in the diagram, which represents, necessarily with enormous exaggeration, its deviation, OQ, from the earth's centre. Now, the actual force on the moon in the line MQ, may be regarded as consisting of a force in the line MO towards the earth's centre, sensibly equal in amount to the whole force, and a comparatively very small force in the line MT perpendicular to MO. This latter is very nearly tangential to the moon's path, and is in the direction *with* her motion. Such a force, if suddenly commencing to act, would, in the first place, increase the moon's velocity; but after a certain time she would have moved so much farther from the earth, in virtue of this acceleration, as to have lost, by moving against the earth's

perpendicular to MO.

This latter is very nearly tangential to the moon's path, and is in the direction *with* her motion. Such a force, if suddenly commencing to act, would, in the first place, increase the moon's velocity; but after a certain time she would have moved so much farther from the earth, in virtue of this acceleration, as to have lost, by moving against the earth's

attraction as much velocity as she had gained by the tangential accelerating force."

The consequences are then shown to be that the moon's distance would be increased in the ratio 1 : 1.46, and her periodic time increased, and the earth's period of rotation lengthened.

This reasoning perplexes me; for if the effect of a certain amount of fluid friction is to throw the line of action of the force from MO to MQ, a fluid friction is conceivable which should throw it outside the earth altogether. Moreover, the line of attraction of the earth on the moon would be in a line not passing through the earth's centre, a result I cannot understand, especially if the fluid friction were increased as just suggested. Nor can I see that a force in MQ, the centre of the earth being free, would tend to stop the rotation of the earth.

As I view the matter, fluid friction generates a *couple* tending to stop the rotation of the earth, and it is impossible to combine this couple with the force in MO, and represent the resultant by a single force. The energy lost in the form of momentum of rotation of the earth is gained in the heat devolved by the fluid friction, which is ultimately dissipated. And the final result would be that the orbit of the moon would not be appreciably altered, while the period of rotation of the earth is gradually lengthened.

Am I wrong, for the thousandth time in my life? and if so will some one try and enlighten me. Perhaps Prof. Tait will spare a few minutes to an old friend.

M. A.

Circumpolar Lands

IN NATURE (Feb. 8) Mr. Murphy seems to admit the soundness of the reasoning by which I endeavoured to show (Jan. 25) that the earth's form is probably undergoing a slow progressive change, but he thinks that the statements in the first and last parts of my letter are contradictory.

If Mr. Murphy will be good enough to read again the paragraph immediately following the one which he quotes, I think he will find that there is no contradiction. "Transmission of pressure towards the poles" must tend to elevate the land in those regions. How that pressure is produced and transmitted I have endeavoured to show in the same paragraph.

However, the main proposition which I sought to establish in my paper of 1857, before alluded to, is, that any spheroid of equilibrium, whether earth, sun, or any other, in motion about an axis, in cooling from a fluid state, undergoes a change of form, and with this proposition Mr. Murphy seems to agree.

Mr. Murphy has inadvertently omitted part of a sentence in making his quotation from my letter, thus representing me as speaking of a *ratio* with *one* quality only.

Queen's Coll., Liverpool, Feb. 16 GEORGE HAMILTON

The Spheroidal State of Water

I HAD the pleasure a few days ago of visiting Messrs. Johnson's celebrated iron wire manufactory in Manchester. There may be seen a series of furnaces and rolling mills which in twenty-four hours can convert a truck load of the best Swedish iron into the bright and polished galvanised wire which is now being so extensively employed to complete our very perfect system of Post Office telegraphs. Every stage of the process passes beneath the eye of the observer; the melting of the pigs, the formation of the billets, the puddling of the bloom, the shingling of the balls, the rolling of the bars, and their subsequent extension by further rolling, and drawing into telegraph wire.

The bars are cut off into 10ft. lengths, and are placed in a Siemens' regenerative furnace, where they are raised to a brilliant white heat. They are then drawn out of the mouth of the glowing furnace, and pass through a series of consecutive rollers of varying dimensions, and rotating with varying speed, ultimately flowing out in a continuous stream of iron wire. In fact, the metal is at such a high temperature and so plastic that the curves it takes in falling convey the idea of a thin, fine unbroken jet of liquid metal.

The rollers are kept cool by the constant play upon them of jets of water. The first pair of rollers is fixed close to the mouth of the furnace, which is partially closed by a moveable screw that is only raised when the attendant sprite requires to direct another bar to the attenuating process of the continuous rollers. The jet of water that cools the first pair of rollers in one furnace fell in a broken shower upon the foot-plate of the mouth of the furnace, which, from its proximity to the fire, was raised to a

very high temperature, and therefore converted the drops of water into the spheroidal state. There they bounded and danced and rolled about like pith balls under an excited electrical receiver. Their constant rotation and well-known rippling motion gave them an opaque appearance which caused them to resemble closely a fine fall of hail. In fact, those to whom I pointed out the phenomenon likened their appearance to a fall of dusty snow at the mouth of a furnace. The sight was very striking and interesting. The workmen had taken these spheroids to be particles of scale and dust swaying about in the currents of air at the mouth of the furnace.

I have seen many times the experimental illustration of "Leidenfrost's phenomenon" at the mouth of a furnace, but I had never before seen its practical, though accidental, development, and in the incident which I have narrated above the interest chiefly attaches to the great antithesis of the fact and its appearance—snow at the mouth of a fiery furnace.

W. H. PREECE

The American Eclipse Expedition

I DEEM it but proper and just that I should correct a mistake that has just met my eye in Dr. Schellen's excellent work on Spectrum Analysis.

On page 332 of the 2nd German edition we find "Die erstere Expedition wählte unter der Anführung von Professor Morton die Burlington im Staate Iowa."

"(1) Burlington mit den Beobachtern Professor Mayer, Kendall, Willard, Phillips, und Mahoney, denen sich der als gewandter Spectroskopist bekannte Dr. C. A. Young, Professor am Dartmouth College (Hanover), und Dr. B. A. Gould für die photographischen Aufnahmen hinzustellen."

In the English translation, edited by Mr. Huggins, the above reads, "The first expedition, under the guidance of Professor Morton, selected stations in the State of Iowa as follows:—

"(1) Burlington, where its observers were Professor Mayer, and Messrs. Kendall, Willard, Phillips, and Mahoney, together with Dr. C. A. Young, Professor of Dartmouth College (Hanover), well known as an experienced spectroscopist, and Dr. B. A. Gould, to whose charge the photographic department was committed."

Dr. Gould had no connection with the photographic expedition, but placed himself under Professor Coffin's general organisation, so that he could have facilities for making observations on the corona, and in searching for the suspected intermercurial planet.

The Burlington station of the Philadelphia eclipse expedition was placed under the direction of Dr. Mayer, and the photographs pointing page 337 of Dr. Schellen's work are two of the five plates secured by him during totality.

Also the diagram on page 338 is from Dr. Mayer's report on the eclipse (published October 1869), an abstract of which, with accompanying copies on glass of the original negatives, was presented by M. Delaunay to the Institute of France. The Rev. T. W. Webb laid them before the Royal Astronomical Society, when the report and the photographs were discussed at length at the meeting of November 12, 1869.

HENRY MORTON, President

Stevens Institute of Technology, Hoboken, New Jersey

Mr. Spencer and the Dissipation of Energy

WILL you permit me to inquire, for the instruction of the many who are familiar with Mr. Herbert Spencer's "Doctrine of Evolution," and especially in regard to "First Principles," sec. 58, referred to by Mr. Spencer in his paper in your number for February 1, if the theory of the "Dissipation of Energy" does not upset a very considerable and significant portion of Mr. Spencer's "First Principles"? WILLIAM SMYTH

Maidstone, February 12

THE AURORA OF FEBRUARY 4

ON Sunday, the 4th inst., was witnessed one of the most magnificent displays of aurora which have been seen in Europe within the past twenty or thirty years. To most observers in this country it appeared equal in magnificence to the two fine auroræ seen on Oct. 24 and 25, 1870, and which were especially grand in

England; but foreign observers could only compare it with those seen in 1831 and 1836. But if we take all the attendant phenomena into consideration, it will appear that, whilst others may have equalled this one in grandeur and beauty, there is not one which can compare with it either as to the wide extent of country over which it was visible, or as to the strangeness of many of the phenomena by which it was accompanied. The numerous letters which have appeared in these columns the last two weeks show how universally it was noticed in England, Scotland, and Ireland; but in addition to these, the letters and telegrams which have appeared in the daily and weekly papers—both English and foreign—show that it excited attention over a still larger area. It is difficult to trace the exact limits of this area; but when we mention Paris, Cologne, Berlin, Malta, Constantinople, Egypt, and India, it will be seen what a large extent of country is embraced. So far we have seen no account of it as having been visible in the extreme north of Europe, as in Iceland, Norway, Sweden, St. Petersburg, &c., where most auroræ boreales are so well displayed; but, on the contrary, many of the cities in which it was noticed are those which are commonly supposed to be too far south for such phenomena to be seen. The importance of this point will appear later on.

To take England first. Mr. Allnatt sends to the *Times* a long description of the appearance of the aurora as seen by him at Frant, which shows that it was first noticed at 6 P.M. in the S.W., and that by 7 o'clock it had reached the zenith. It disappeared at 7.45, but reappeared for a short time at 10.50 in the N.; but "at 7.30 P.M. the whole heavens were pervaded by this abnormal southern aurora, that had now expanded universally and dipped its supplementary bands into the northern horizon." He also writes:—"The earth's electricity was so powerful, that the gold leaves of the electrometer remained diverged for a considerable time!" Other correspondents describe it as seen at Blackburn, in Lancashire, at 7, "embracing the whole southern sky from N.E. round to W.," from Faversham, in Kent, as visible between 9 and 10 o'clock; "from Cambridge as having its maximum intensity about 10; at Swindon as commencing at 10 minutes past 7 and lasting till 10 o'clock, "and giving as much light as a full moon, every object being clearly visible." But many observers had noticed it at times considerably earlier than those just mentioned: thus, "J.S.H.," writing in *NATURE* last week from Gloucester, "observed it at 5.30, just in the twilight, but it was then confused with the rays of the setting sun; but as the darkness deepened the aurora came out alone, and was then extremely beautiful." But still earlier was it observed at Hartlepool, whence a correspondent writes, at 5 o'clock:—"The whole of the southern sky was tinged with a most beautiful rose colour, which, as darkness set in, extended towards the zenith, where it culminated in a brilliant corona." This very early manifestation of the aurora partakes very much of the nature of a "day aurora," the possibility of which has been so much discussed in these columns (*vide NATURE*, vols. iii. and iv.). To us there does not appear much difficulty in believing that these grand meteorological phenomena, whatever their cause may be, are independent of merely relative time, and that the reason why they are mostly observed at night is because the purely local circumstances are then most favourable to their observation. That an aurora should wait till night-time before it manifests itself hardly seems probable, whilst, on the other hand, that the more brilliant light of the sun should prevent auroral displays being seen in the day-time is not only probable but is borne out by what we know of the light of the stars and planets. No one believes that stars only shine at night-time, why then should there be a belief that auroral displays take place only at night-time, especially when it is remembered that the experiences of polar travellers in their sunless regions are distinctly against it? But this is a digression arising from the fact that in comparative daylight we have distinct and independent evidence of this aurora having been observed. In addition to those already

given, from Worcester we learn that it was noticed "shortly before 6 o'clock in the twilight, when thin fleecy clouds of a bright rose colour were observed in the South and East," whilst correspondents of the *Kölnische Zeitung* state that it was first noticed at Cologne about 6 o'clock, and at Bonn about "half-past 5, gradually becoming more and more marked till 6 o'clock, when do doubt was left as to its true auroral character."

While there is thus clear evidence that the phenomena had commenced some time before 6 o'clock, there is, as might be expected, great diversity as to the time when it was last visible. That this should be the case is only natural, and is entirely dependent on purely local circumstances—the state of the weather, the cloudiness of the sky, &c. Thus, whilst in some the aurora first appeared at 6 o'clock, to others it was not visible till between 7 and 8; and whilst in some places it disappeared about 8 or 9, it was then in others in its most brilliant state. But, taken as a whole, it appears to have lasted the whole evening until quite late at night; thus a correspondent, writing to the *Pall Mall Gazette* from Autun, states that "at midnight the East was crimson, and it was so light that I could tell the time easily, although my watch has gold fingers, and strong shadows were cast in rooms whose windows faced the East."

We have thus evidence of the aurora having commenced about 5 o'clock, and continuing at least till midnight, and probably later. But before proceeding to notice the other attendant phenomena, we would direct attention to a passage in the letter of the correspondent of the *Pall Mall Gazette*, before alluded to, which confirms the hypothesis that the accounts of "showers of blood," &c., mentioned in ancient chronicles were in reality only auroral displays. He writes, "all these signs and wonders produced a considerable effect upon the peasantry, who see in them warnings of a coming war; they always connect the idea of a red aurora with bloodshed." Comparing, then, all the varied accounts to which we have referred, we find very general agreement with regard to certain phenomena, some of which are of very remarkable character. The first of these is that when the aurora was noticed by those who observed it early in the evening, it appeared in the Southern and South-Western horizons, thence it seems gradually to spread, and finally appeared later on in the evening in the Northern and Eastern horizon. That this was the case is shown by the agreement of the accounts, some of which we have already quoted, and many more of which might be given. Thus at Bonn, "nothing remarkable was to be noticed on the northern horizon, whilst on the southern lay the dense, greyish bank of clouds, whence auroral streamers shortly ascended." There can also be little doubt that during the middle of the evening, and towards midnight the chief seat of the display was to the north and east, as shown in the letters of those who first observed the phenomena at about 7.30 to 9 o'clock, and continued to do so till towards midnight. The second well-marked phenomenon was that between 7 and 8. There appeared a brilliantly-coloured arch, extending across the heavens from S.W. towards the north and east. Thus at Autun we have described "a splendid and perfect arch, spanning the sky from a point on the south-eastern horizon to one on the south-western, and which lasted, more or less continuously, for two hours, whilst from 10 to 12 the sky became gradually less luminous in the south, and grew more and more splendid overhead. Till about 11 the two eastern and western auroras united in a vast arch overhead, with tongues of green flame darting through a suffused crimson." Similarly other accounts, with merely local variation. The third well-marked phenomenon appears to have been the formation of a "corona," nearly, if not quite, in the zenith, whence auroral rays streamed out in all directions. At some places this was more marked than at others, but is more or less universally noticed, both by English and foreign observers. Thus at Cardiff it is reported that "a corona, having rugged, sharply-defined edges, stood out prominently in the zenith, apparently on a parallel plane to the earth, and having its centre almost immediately over the head of the spectator, rays from which extended to the N.E. and N.W.

horizons." If one may venture to say so, most aurora visible in our latitudes appear to commence in general by an accumulation of cloud masses towards the magnetic north, then coloured masses slowly appear, and afterwards rays, or streamers, are sent up from this northern horizon towards the zenith. Sometimes the coloured masses themselves rise toward the zenith, and there the streamers pass in all directions. But in this aurora of the 4th of February, all the most marked phenomena are directly contrary to our ordinary experience, and should therefore be carefully noted. It is an extremely interesting inquiry to ascertain whether on the evening of the 3rd or 4th instant a brilliant Aurora Australis was visible in the southern hemisphere. If we consider the wide extent of country over which the aurora which we are describing was visible, the probability becomes very great that this will be found to be the case. The question then arises, Was the aurora of Feb. 4th, appearing as it did first in the southern horizon, an Aurora Australis or not? It is impossible to answer this question definitely; but we would throw out the following suggestion:—Knowing the ultimate connection that there is between northern and southern aurora, and the fact that one of any magnitude rarely happens without the other, may we not have seen the last traces of a grand Aurora Australis, which gradually died away, whilst at the same time an Aurora Borealis was in process of formation, and which appeared in its full brilliancy in the northern and eastern horizon towards the latter part of the evening? We would make this suggestion with all due deference, but it seems to us to account in a fairly satisfactory manner for most of the very unusual and peculiar phenomena noticed, viz., the first appearance of the aurora in the south, the grand arch, the corona in the zenith, and the final disappearance in the north. We must also remember that in what is called the correspondence of northern and southern aurora, there must be at least twelve hours difference as regards time. So that if there was an Aurora Australis on the same day, it would be dying out at the time our display was commencing.

In conclusion, the wide extent of country over which this aurora of the 4th February was visible, is easily shown. In Paris a "magnificent aurora" is reported, at Nancy and Chautmont there was a "brilliant display," while the Franco-German telegraph lines were greatly disturbed. At Constantinople one telegram states that "a splendid aurora, extending over half the heavens, was visible for several hours;" whilst another states that it was seen "from 10 till half-past 11." From Alexandria we hear that "a large space of the skies was illuminated for five hours." That it was visible at Malta, Suez, and Bombay, the following interesting account shows. It is supplied by Mr. George Draper, of the British Indian Submarine Telegraph Company, under date of Feb. 5th, and it also shows how powerful were the "earth currents" which were noticed in connection with this most brilliant aurora. He writes:—

"It may interest your readers to know that the brilliant aurora which was visible in London last night was also visible at Bombay, Suez, and Malta. Our electrician at Suez reports that the earth currents there were equal to 170 cells (Daniell's batteries), and that sparks came from the cable. These electrical disturbances lasted until midnight, and interrupted the working of both sections of the British Indian cable between Suez and Aden, and Aden and Bombay. Since Thursday last the signals on the British Indian cables have been very much interfered with by electrical and atmospheric disturbances, causing considerable delay in the transmission of messages, which all efforts failed entirely to overcome. Our superintendent at Malta also reports that there was a very severe storm there yesterday morning, so much so that they were compelled to join the cable to earth for several hours. He also reports the aurora as very large and brilliant. The electrical disturbances on the cables in the Mediterranean, and on those between Lisbon and Gibraltar, and Gibraltar and the Guadiana, were also very great. The signals on the land line between London and the Land's End were interrupted for several hours last night by atmospheric currents."

Taken, then, on the whole, this aurora of February 4th was one of the most brilliant, most interesting, and most widely visible which has been witnessed for many years past, and is probably one that will cause renewed attention to be paid to the still unsolved problem of their causes.

J. P. EARWAKER

[We have also received the following from J. W. Spengel of Berlin:—"At Berlin, the sky being covered by clouds, no one could see anything. But a young astronomer of our observatory told me that he had recognised the existence of a mighty aurora by means of the spectroscope. The magnets were also vehemently disturbed, and all the telegraphs failed for several hours. The following appears in the *Leipsiger Allgemeine Zeitung* for Feb. 8:—Freiburg, Feb. 6. The aurora observed by many on the evening of Sunday caused here a complete interruption of communication through the telegraph wires for some time. The intensity between 5.40 and 6.45 overcame the strength of the battery at this station, so that it was not possible to change the oscillations of the magnetic needle caused by the earth-stream. After the northern light had become fully developed the oscillations became stronger, and followed one another at short intervals until the phenomena entirely 'disappeared about 7 P.M.' At Warmbrunn in the Riesengebirge, the aurora was seen magnificently from 6 to 8.30. Towards 10 it had almost disappeared. The thermometer indicated 0° C., with a violent storm from the south-west. About 11 the storm suddenly subsided; the thermometer fell to -1.5°, and the aurora appeared for the second time in the same manner and with the same uninterrupted play of colours as at 6. After 11.30 the storm recommenced, and the aurora disappeared soon after 12. The play of the aurora on the snow-covered mountains is described as one of the most magnificent sights that can be conceived."—Ed.]

REFERENCE SPECTRUM FOR THE CHIEF AURORA LINE

WHILE Nature herself seems to delight in surrounding some questions with triple difficulties and mysteries almost inscrutable, there are other questions which she has made the easiest of the easy if men will only use the means which she has prepared. And amongst such easy questions, no more signal example can be quoted than the exact spectrum place, within very narrow limits indeed, of Angström's yellow-green aurora line, whenever any aurora at all appears.

This chief aurora line coinciding precisely (as I believe I may say from my own observations, though by means of the roughest of home-made apparatus) with the second line, at W.L. 5579, of the citron band of the blue base of flame, from any and every material used for artificial illumination by man, and having immediately on one side the 1st line, of the same strength with itself, at W.L. 5630, and on the other side the fainter 3rd line, at W.L. 5535, of the same citron band; the smallest variation of spectrum place in the aurora line can be instantly perceived by the eye on this chemical scale, without the aid of any mensuration apparatus.

And yet in your last impression a respectable spectroscopist, after much labour, informs the Academy of Sciences in Paris, on Feb. 5, that Angström's yellow-green aurora line is somewhere close to Fraunhofer's solar line E, *i.e.* W.L. 5269; and in your previous impression a returning Indian observer considers the same Angström line to be somewhere near F, or W.L. 4860. Now, not only are these statements in error to the extent of from 30 to 70 times what they need be, but they cruelly drag us backwards in what should be the always onward course of science, and cause men to flounder once again in that slough of confusion they were immersed in a couple of years ago, when the chief solar corona line, at W.L. 5316,

and Angström's grand aurora line, at W.L. 5579, were stated to be one and the same line, in the same place.

Excuse may, indeed, be proffered for these two observers, that they did not know of such a convenient night reference-spectrum as that which I have now alluded to; and then comes the question as to whose fault was that.

A full description of the method (after extensive trial for several months) was sent by me to the Royal Astronomical Society on May 30, 1871, with the particular request that the paper might be read at their June meeting and printed in the June Monthly Notice. This was mainly with the hope of supplying some possibly useful hints to the intending eclipse-corona-observers of December. The paper, however, though taken in, was neither read at the June meeting (if I am rightly informed) nor did it appear in the June Monthly Notice; but was handed over to secret referees, who simply sat upon it during six long months—or until the eclipse was safely past, and then they began to hint about possible objections being likely to be taken against some parts of the paper.

Of course I could not allow so admirable a society to run any risks of which they were afraid on my account; so I withdrew the paper thereupon, and am now engaged in publishing it myself, sustained in so doing by the hope that, although the eclipse for which it was mainly intended is irretrievably gone, its pages may yet be useful to some spectroscopists of aurora; and, in fact, that through their influence certain of both French and English observers will cease to attempt comparing the faint aurora's chief line with a bright solar spectrum, which they can never see in combination therewith (and if they could it has no coincident lines), but with a cheaply-procured chemical spectrum, which only comes well into view under the darkness of night, and is gifted by Nature in the spectroscopist with an easily recognisable line in apparently absolute coincidence with the cosmolical line of Angström.

C. PIAZZI SMYTH

15, Royal Terrace, Edinburgh, Feb. 16

AMERICAN DEEP-SEA SOUNDINGS*

UNDER the title at foot a pamphlet of thirty-three pages, accompanied by a large chart, and illustrated by several diagrams and tables, has been issued. The school-ship *Mercury* is a vessel belonging to the commissioners having in charge the hospitals and prisons of New York city, and is employed for the purpose of training boys, committed by the magistrates for vagrancy and slight misdemeanours, to become thorough seamen. Instead of growing up to be a curse to the community, such boys are made into valuable men. The adventurous life has a special charm for them.

An essential feature of the discipline on this ship is to make long cruises, by which the boys are fitted quickly to enter into the service of the navy or mercantile marine. Of 258 boys carried out on this voyage, 100 were on the return of the ship, in the opinion of the captain, capable of discharging the duties of ordinary seamen.

The commissioners, in addition to the above object, desiring to advance the interests of science as far as lay in their power, instructed the captain, P. Giraud, to obtain a series of soundings on the line of or near the equator, from the coast of Africa to the mouth of the Amazon, to observe the set of the surface currents and the temperature of the water at various depths. He was also directed to bring home specimens of water and of the sea bottom.

The ship sailed on December 20, 1870, and arrived at Sierra Leone on February 14. On February 21 she left

* Cruise of the school-ship *Mercury* in the Tropical Atlantic, with a Report to the Commissioners of Public Charities and Correction of the City of New York on the chemical and physical facts collected from the deep-sea researches made during the voyage of the nautical school-ship *Mercury*, undertaken by their order in the Tropical Atlantic and Caribbean Sea, 1870-71. By Henry Draper, M.D., Professor of Analytical Chemistry and Physiology in the University of New York.

Sierra Leone, and the soundings and other observations were continued till she reached Havanah, April 13, 1871.

The papers, together with the various specimens, were placed in the hands of Professor Henry Draper, of the New York University, for examination. His report commences by stating "that much attention has recently been given to deep-sea researches in consequence of the investigations made by the United States government on its coast, and by Dr. Carpenter, Mr. Gwyn Jeffreys, and Prof. Wyville Thomson, in the North Atlantic and Mediterranean Sea. Not only have many of the facts so ascertained been corroborated by this voyage of the *Mercury*, but the commissioners, by authorising it, have added much that is new and interesting to our knowledge of the physical condition of the deep sea."

Then follows a discussion of the barometric variations, in which it is shown that they were very small in crossing the ocean, the minimum being only $\frac{1}{16}$ below, and the maximum $\frac{1}{16}$ above the mean. In a general manner the pressure increased on nearing the American coast.

The currents varied from south near the African coast by south-west to west near the American coast, and their velocity was on an average above half a knot.

Some general remarks on the sounding apparatus (Brook's detaching apparatus) and water-collecting cylinder are next made, attention being more particularly directed to the incorrect conclusions that the latter is apt to lead to. "The constitution of the water as it exists at great depths is not correctly represented by the sample thus obtained. A considerable portion of the gases dissolved therein may escape under the relief of pressure as the cylinder is drawn to the surface, and hence examinations of such samples as regards their gaseous ingredients are liable to be deceptive. Even the saline ingredients will suffer disturbance when they are held in solution by gases that will thus escape; for instance, this is the case with carbonate of lime." Table iv. shows the specific gravities of the samples of sea water from the surface and at various depths to 420 fathoms; Table v., the air temperature between Sierra Leone and the Florida capes; Table vi., the temperature of the air, sea surface, and of the water at various depths. The thermometer was of Six's form, without index error when compared with a standard Kew instrument, but not protected on the Miller-Casella plan.

A diagram of the bed of the Atlantic Ocean at the twelfth parallel of latitude is introduced, based on fifteen soundings. It shows that "parting from the African coast the bed of the ocean sinks very rapidly. A couple of degrees west of the longitude of Cape Verde the soundings are 2,900 fathoms. From this point the mean depth across the ocean may be estimated at about 2,400 fathoms, but from this there are two striking departures—first a depression, the depth of which is 3,100 fathoms, and second, an elevation at which the soundings are only 1,900,—the general result of this being a wide and deep trough on the African side, and a narrower and shallower trough on the American. It may be that this peculiarity is a result of the river distribution on the two continents respectively, there being, with the exception of the Senegal and Gambia, no important streams on the African side, whilst on the American there are many, and among them pre-eminently the Orinoco and the Amazon, these vast rivers carrying their detritus far out to sea and helping to produce the configuration of the ocean bottom in question. However this may be, it is doubtless through these deep troughs that much of the cold water of the north polar current finds its way."

"In accordance with this we perceive, on examining the temperature of the water after the African verge of the greater or eastern sea trough is reached, that there is a difference in temperature between the surface and that at a depth of not more than 200 fathoms exceeding 25° in many cases. This decline of temperature increases as

the depth increases, one observation giving an additional fall of 4° at an additional depth of 200 fathoms. It is not, however, intended to affirm that the mass of cold water is restricted to these deep troughs, since even in the West India seas at similar depths low temperatures are observed, and this though the heat of the surface water had become very much higher. In those seas while the surface temperature was 84° the thermometer at depths of 400 and 500 fathoms marked 48° ; and these it must be remembered were the indications of an uncompensated instrument which was bearing a pressure of at least half a ton on each square inch of its surface, and hence registering degrees that were higher than the truth. This accords with the observation of Mr. Barrett that in the deepest parts of the sea near Jamaica there exists a temperature not far above that of the freezing point of fresh water." Accompanying these remarks is a diagram showing the curves representing the temperature of the air, surface of the water, and deep water during the voyage, and that is followed by a diagram of the specific gravity of surface and deep water.

"The general conclusion which may be drawn from these results as to temperature and specific gravities is that there exists all over the bottom of the tropical Atlantic and Caribbean Sea a stratum of cold water—cold since its temperature is below 50° . This is the conclusion to which Dr. Carpenter has come as respects the Atlantic in higher north latitudes; and in this important particular the cruise of the *Mercury* must be considered as offering confirmatory proof of the correctness of the deductions drawn from the cruises of the *Lightning* and *Porcupine*."

"There are reasons for supposing that, so far from this water being stagnant, its whole mass has a motion towards the Equator, whilst the surface waters in their turn have a general movement in the opposite direction."

An analysis of the gaseous ingredients was not attempted, because the specimens had been kept too long and for other reasons that are specified; but in relation to organic matter it is stated: "I made some examinations of the organic matter contained in these waters both by incinerating the solid residue and by the permanganate test. . . . It needed no especial proof that organic matter was present in every one of these samples, for the clearest of them contained shreddy and flocculent material, some of them quantities of sea-weed in various stages of decomposition. With these vegetable substances were the remains of minute marine animals. As bearing on this subject I found on incinerating the solid residue of a sample of water taken from 200 fathoms, that the organic and volatile material was not less than 11 per cent. of the whole. Though the quantity of organic substance diminished as the structure under examination was deeper, there still remained a visible amount in the water of 400 or 500 fathoms. It is probable therefore that even at the bottom of the ocean such organic substance may exist, not only in solution affording nutriment to animals inhabiting those dark abysses as Prof. Wyville Thomson has suggested, but also in the solid state. Plants of course cannot grow there on account of the absence of light."

"In order to determine whether any hitherto unknown element existed in these waters, I subjected the solid residue to examination with the spectroscopic, volatilising the substances by the aid of a voltaic current and induction coil. A careful examination did not reveal the presence of any spectral lines other than those belonging to the well-known elementary substances in sea-water."

"The specimens of the bottom, obtained by attaching to the sounding line quills or wooden tubes, I have transmitted to Dr. Carpenter, who has kindly consented to examine them. In a letter recently received he says, 'As far as I can see they consist of the ordinary Atlantic mud, chalk in process of formation, with the ordinary types of deep-sea foraminifera.'"

THE RECENT AURORA, AND A NEW FORM OF DECLINOMETER

ON Sunday night, the 4th of February, we saw here the magnificent coloured Aurora Borealis, which has been described in NATURE, in the newspapers, and which, I see from telegrams, has been observed at very distant stations. Indications of the aurora were noticed here soon after sunset; but about 6.45 P.M. the whole eastern portion of the sky became illuminated with red light, at first faint, but rapidly becoming more and more intense, while yellow streamers began to shoot up from the north-eastern arc of the horizon nearly to the zenith. About the south-west there was also much red and yellow light; it was spread over a large apparent area, but was not so intensely bright or so strongly coloured as that which lay to the north-east. It too, however, possessed splendid broad, yellow streamers. The display lasted in full beauty till about 7.20, but long after that time much red and yellow light with occasional streamers was to be seen.

It is strange that the phenomena of the Aurora Borealis still remain so little understood. It would add much to our knowledge, if those who witness these displays would make sketches of the appearances at the time when very definite forms of the streamers are observed, noting also the time of the observation very carefully, and the position of well-known stars and constellations. A comparison of such sketches, and of notes that might accompany them, would give us most important data, and might lead to the determination of the locality of the discharge.

Simultaneous observations, at widely different stations, of the disturbances of terrestrial magnetism that always accompanied the aurora might, if compared, give us useful information as to the direction and velocity of the electric discharge; and would probably at least help us to decide whether it is to the discharges themselves, or to earth-currents, or to both combined, that these disturbances are due.

I wish to describe an instrument planned by Sir William Thomson, which may be easily constructed, and with which the variations of the horizontal component of terrestrial magnetism can be determined with great accuracy.

FIG. 1

A flat wooden support, seven or eight inches high, is fixed on a convenient foot furnished with levelling screws, and in the face of it a groove, rather more than four inches long and about $\frac{1}{16}$ of an inch deep, is cut. From a point at the top of this groove, a very light mirror with magnets attached—such as is used in Thomson's reflecting galvanometer—is suspended by a single silk fibre about four inches long; and in front of the groove there is fastened, if the mirror be concave, a slip of plate glass to keep off currents of air: or, if it be a plane mirror, a lens is fastened in front of it, and the remainder of the groove is covered up with a slip of glass or in some other way. A lamp is placed in front of the mirror, and the reflected image of it is received on a scale. The motions of the reflected light upon the scale indicate the deflections of the magnet.

Suitable mirrors and lenses are constructed by Mr. White, instrument maker, Glasgow. In making the mirrors, a large number of the lightest circular glasses used for covering objects on slides for the microscope are silvered; and from these those which give an image perfectly free from distortion are selected by trial. Many of the mirrors formed are much twisted and quite unfit for use; but mirrors are obtained by this plan of selection

by trial far superior in lightness and in freedom from distortion to any that can be made by expending extreme care in the glass-work. To the back of each mirror four small magnets are attached; an arrangement which has been found by trial to give the best result. The object is to make the mirror with its magnets sufficiently light, and to give it at the same time the greatest possible magnetic moment. The mirror is three-eighths of an inch in diameter, and weighs not more than one-third of a grain.

Plane mirrors are generally used in Glasgow, and the lens is of such power that a lamp placed at a distance of one metre (about 40 inches) gives an image at the same distance from the mirror. The lamp is placed behind a screen, and in the screen an oval hole is cut and a vertical wire* is stretched across it. The image of this wire is received upon a scale. The scale may be set at a distance of 40 inches (one metre) from the mirror; that is to say it

FIG. 2

may be attached to the screen between the mirror and the lamp; or it may be put much farther away, at, say two or three times that distance. The lamp and screen, with its slit and wire, must then be brought near enough to the mirror to throw back the conjugate focus sufficiently. This arrangement gives of course increased sensibility. We use for it a paraffin oil lamp, of which the reservoir is a very shallow rectangular vessel. The slit in the screen is slightly above the horizontal plane through the centre of the mirror, and the scale slightly below that plane. The reflected ray passes below the reservoir of the lamp to the scale beyond.

Our scales, which are also obtainable from Mr. White, are divided into fortieths of an inch, and are generally attached to a piece of wood, cut out so that its curvature corresponds to that of a circle described with the distance of the mirror as radius. Thus, by dividing the number of scale divisions by the distance of the mirror in fortieths of an inch from the scale, the angle is obtained to which that number of scale divisions correspond. At a distance of 60 inches we can easily read the position of the image of the wire on the scale to less than half a scale division, which, since the angle turned through by the reflected beam of light is twice that turned through by the mirror, corresponds to an angular deflection of about $20''$.

The great advantage which the arrangement that I have just described possesses over any that are ordinarily used for observing rapid variation in magnetic declination lies in the lightness of the mass moved. The heavy declinometers employed in observatories are unable, through their great inertia, to follow accurately the sudden variations that occur during a magnetic storm.

JAMES THOMSON BOTTOMLEY

The College, Glasgow

* A simple vertical slit was formerly used, but the vertical wire in the middle of the slit, a suggestion of Prof. Tait, is a great improvement, as it enables us to use plenty of light, while it gives increased precision to the reading on the scale.

THEORELL'S PRINTING METEOROGRAPH

SOME time since brief mention was made of the above instrument (devised by Dr. A. G. Theorell, of Nybrogatan, Stockholm, Sweden—*NATURE*, vol. iv. p. 466)—with reference to its having been exhibited at the London International Exhibition, 1871.

Being in possession of a detailed description of the same, I have thought that a copy with additional remarks may be of interest in the pages of *NATURE*.

I have no hesitation in saying that this instrument does

not occupy the prominent position to which it is justly entitled, neither do I think that it is so well known—whether taken in the light of a wonderful piece of mechanism, or of excellent workmanship—as it well deserves to be.

The following is a description of the instrument in accordance with the original, excepting only that I have made a few slight alterations in order to render it more intelligible, the original having been, as I suppose, translated from the Swedish language, and not well expressed :—

"Meteorological observations are by this instrument delivered in tables printed on a slip of paper. Of the four tabular columns the *first* gives the hours, the *second* the temperature, the *third* the degree of humidity according to August's method, and the *fourth* the atmospheric pressure; this last (atmospheric pressure) is given in millimetres, but the first figure, being always a 7, is suppressed. The degrees of the thermometer employed are those of the centigrade scale, and negative degrees are expressed by their complements to 100.

"The registration takes place by means of electrical currents, which are closed by contact between the mercury in the various meteorological instruments and steel wires that descend into their tubes. These steel wires are connected, by means of levers and three vertical screws, each with its respective system of brass wheels with numerical type engraved on the edges, in such a manner that the rotation of the wheels causes an upward or downward motion of the steel wires, so that the point of the scale on which the lower extremity of the wire is situated, is neces-

sarily that indicated by the number appearing at the same moment uppermost on the corresponding wheels.

"The wheels containing the figures are governed by an electro-magnetic motor, which, for each observation, sets the three wheel systems successively in motion, until the corresponding wires have reached the mercury in their respective meteorological instruments, when the above-mentioned electrical current instantly arrests the motion, so that accordingly all three steel wires stop with their lower extremities each in contact with the surface of the mercury in its respective instrument. The numbers therefore that stand uppermost on the numbered wheels are just those which indicate the height of the barometer and of the two thermometers, and now the same electro-magnetic motor operates upon a printing apparatus which, after having deposited colour on the type, presses the slip of paper against them. This being done, the steel wires are drawn up again by the motor, which stops as soon as a certain distance from the mercury is attained, and all is ready for the next observation.

"The interval between the observations is a quarter of an hour."

Attention is then directed to the following considerations:—

"The instrument delivers the observations in a form in which they may immediately, and without further modification, be used by the meteorologist in his work.

"A very large number of very carefully made comparisons have shown that the observations registered by this method possess an accuracy equal to that which is generally attained by ocular observation.

"The zinc vessel, in which the upper ends of the thermometers are enclosed, is so air-tight that it is found possible, by means of chloride of lime and caustic potash, to keep the enclosed air always free from damp and carbonic acid, a precaution which it will be easily understood is necessary in every climate where the temperature is liable to sink below the freezing-point, but is still further necessary to protect both the mercury and the steel wires from oxidation, and thus preserve the galvanic contact.

"A meteorograph of this construction has for two years and three-quarters been in use at the Upsala Observatory, executing six observations every hour, without any perceptible alteration of the surface either of the mercury or the steel wires, that could in any way affect either the free efficiency of the instrument or its degree of accuracy, which throughout the whole time has been found to be that above named.

"As the clock which determines the time of the observations does not require winding up—the instrument itself restoring the tension of the mainspring every quarter of an hour—it continues to go as long as the driving force, *i.e.*, the electrical current, is maintained; and, as the slip of paper applied lasts fully three months, it is clear that that is the period for which the instrument may be left to itself. The work then requisite is little more than to take out, cut, and sew up in order the paper of observations, and replace it with another slip. We thus see that this instrument requires but very little time and labour of the person who takes charge of it.

"It is entirely for special reasons that the construction of the instrument has been limited to the registration of thermometrical, psychrometrical (hygrometrical), and barometrical observations, for the method may be applied advantageously to observations of the course of any phenomena whatever, provided they can be indicated by an index admitting of galvanic contact. It is, therefore, applicable for all the now usual kinds of meteorological observations, and nothing prevents the same instrument executing and printing them all in one and the same table."

The following is an extract (giving one hour's instru-

mental readings) of one of the printed forms referred to in the first paragraph:—

1	.	.	57	.	.	130	.	.	673
			57	.	.	1305	.	.	9725
			57	.	.	132	.	.	672
			57	.	.	133	.	.	673
2	.	.	57	.	.	1335	.	.	672

The width of the slip of paper used in these observations is 4 $\frac{1}{2}$ in.

In the Exhibition meteorograph, the timekeeper (referred to in the eighth paragraph) is merely a watch-movement of moderate size.* In the place of the ordinary minute-hand there are four, fitted on the same centre and projecting from each other at right angles in the form of a cross; in other words, the points (one of which resembles what is technically termed a *spade* hour hand, and indicates the time) are 15 min. apart. Every time one or other of the hands comes opposite the figure III. it depresses a small steel lever which, through suitable mechanism, completes the circuit.

I am indebted to Dr. Theorell for a very courteous letter, dated from Upsala, respecting the block used in the original description, also to Messrs. Norstedt and Son, printers to the Swedish Government, for supplying me with an electrolyte copy of the same through the Swedish Consulate.

JOHN JAMES HALL

ON SLEEP†

PROFESSOR HUMPHRY commenced his lecture by giving a brief account of some of the changes that take place in the tissues when their function is active, and explained that during this time a slight deterioration of structure takes place, which, affecting the voluntary system, the muscles and hemispheres of the brain, causes the sense of tiring, and necessitates a period of rest for the restoration of the tissues to their former condition. In the case of the muscles this rest is provided for by periods, quickly alternating periods, of action and cessation of action. But in the case of the brain, the actions upon which consciousness, volition, &c., depend cannot be thus frequently suspended. Their continuance is needed for the safety of the body during long periods, through the whole day, for instance; and longer periods are therefore required for repair. These are the periods of sleep.

He next took a cursory glance at the different parts of the nervous system, explaining that the upper regions of the brain are those which minister to consciousness and volition, the intellectual operations, &c. He showed that the functions of these regions not only can long be suspended without interfering with the action of the lower parts of the brain, which are more immediately necessary to life; but that they are very easily suspended—slight causes, such as a jar, or a shock, or an alteration in the blood current, being sufficient to stop the action of these parts and deprive the person of consciousness. The spontaneous stopping of their action, consequent on the slight deterioration of their structure from the continuance of their functions during the day, is the proximate cause of sleep during the night; and the periodic recurrence of sleep is in accordance with the periodicity observed in several of the nutritive functions, and, indeed, witnessed in many of the other operations of nature.

After observations upon the condition of the brain during sleep, the circumstances that conduce to sleep, the time that should be allotted to it, and other points, the Professor entered at some length into the subject of dreams. These he regarded not, as has been supposed by some, to be a necessary attendant on, or feature of, sleep, but rather to be the result of an abnormal condition. In the natural state we should pass from wakefulness to complete uncon-

* On the other side of the instrument to that seen in the engraving.

† Abstract of a Lecture delivered at the Royal Institution, on Friday, February 9, by Prof. Humphry.

sciousness, and *vice versa*, quickly, almost instantaneously, and many persons habitually do so. But the transition period is sometimes prolonged, and stages are observable. The first thing that occurs is the lowering, or cessation, of that control over the mental processes which is the highest of our powers, the one requiring the greatest effort, and the one most easily lost. In this condition the thoughts ramble unchecked, chase one another confusedly over the mental field, and give rise to all sorts of incongruities of the imagination. At the same time, being unrestrained, they are excited, and evince efforts of memory and even of combination, of which, in the regulated state of wakefulness, they are quite incapable. In this way the images of persons and places, events, and items of knowledge, long forgotten in the ordinary state, are recalled with distinctness, and we fancy that new information has been acquired when it is only forgotten facts that are recalled. He did not agree with the physiologists who conceive that dreaming depends upon an inequality in the condition of different parts of the brain, some being excited or wakeful, while others are quiescent or asleep. He rather took the view that all the parts of the cerebral hemispheres combine in each of the efforts of control, consciousness, memory, and other mental acts, that all suffer alike from those efforts, alike need the restoring changes which take place in sleep, and, together, *pari passu*, pass through the stages on the way to and from sleep, in which dreaming, sleep-walking, &c., occur.

NOTICE OF THE ADDRESS OF PROF. T. STERRY HUNT BEFORE THE AMERICAN ASSOCIATION AT INDIANAPOLIS *

IN a brief notice of the recent address of Prof. Hunt, it is stated that, while the discussions show learning and research, and his review of the progress of opinions with regard to the Taconic and associated rocks is an able presentation of the subject, its conclusions are throughout open to doubts and objections. Since it is fairer to an author to make special, rather than general, criticisms, I propose to state here a part of the objections referred to in that remark. They are as follows:—

1. That, while accepting the ordinary views with regard to most "pseudomorphs by alteration" (crystals chemically altered without a loss of form), he rejects them with respect to those that are silicates in composition; that is, he denies that the crystals of serpentine having the form of chrysolite, pyroxene, dolomite, &c., are pseudomorphs; and the same of those of steatite, having the form of hornblende, pyroxene, spinel, &c.; of those of pinite having the form of nephelite, scapolite, &c.; and so in other cases:—notwithstanding that (1) they bear positive evidence of change in having ordinarily no polarising properties, and no other interior features or qualities conforming to the external form; that (2) the crystalline forms are just those presented by the species after which they are supposed to be pseudomorphs, and the idea of their being real forms of a single polymorphous species is wholly inadmissible, as pronounced by every crystallographer who has written on the subject; that (3) the pseudomorphs show all stages in the process of change from incipient to complete alteration, in the latter case not a trace of the original mineral remaining.

In this assumption, for it is little better, he opposes the views of every writer on pseudomorphs, excepting one—Scheerer; and Scheerer's chemical speculations, which are at the basis of his opinions, he rejects, like all other chemists.

This unwarranted assumption has a profound position in the system of views on metamorphism which Prof.

Hunt holds, and gives shape and intensity to his opinions of the views of others.

2. That, in commencing a paragraph with the sentence, "The doctrine of pseudomorphism by alteration, as taught by Gustaf Rose, Haidinger, Blum, Volger, Rammelsberg, Dana, Bischof, and many others (meaning thereby other writers on pseudomorphism), leads them, however, to admit still greater and more remarkable changes than these, and to maintain the possibility of converting almost any silicate into any other"—he grossly misrepresents the views of at least Rose, Haidinger, Blum, Rammelsberg, Dana; and that he completes the caricature in the closing sentence of the same paragraph, in which he says, "In this way we are led from gneiss or granite to limestone, from limestone to dolomite, and from dolomite to serpentine, or more directly from granite, granulate or diorite to serpentine at once, without passing through the intermediate stages of limestone and dolomite;" part of which transformations, I, for one, had never conceived; and Rose, Haidinger, Rammelsberg, and probably Blum and the "many others," would repudiate them as strongly as myself. Next follows a verse from Goethe, that is made to announce his personal vexation with their "sophistries;" *alias* absurdities, as the context implies.

Prof. Hunt's rejection of established truth alluded to under sec. 1 here manifests its effects in leading him to misrepresent—although unintentionally—the views of writers on pseudomorphism; and to add to his misrepresentation by means of the strange conclusion, that, because such writers hold that crystals may undergo certain alterations in composition, therefore they believe that rocks of the same constitution may undergo the same changes; as if it were not possible that external or epigenetic agencies might reach and alter crystals under some circumstances of position, when they could not gain access to great beds of rock. Haidinger, the eminent crystallographer, mineralogist, and physicist of Vienna, and one of the most prominent writers on pseudomorphism, never wrote upon the subject of the alteration of rocks at all, and this is true of others, against whom the above charge is made by Mr. Hunt.

With a little clearer judgment, part at least of that vexation of spirit which required the help of a great German poet, and the German language, adequately to express, might have been avoided.

3. That he charges me with the opinion of Bischof, that "regional metamorphism is pseudomorphism on a grand scale;" when I make no such remark, neither express the sentiment, in my Mineralogy of 1854, in which I give an abstract of Bischof's views and make my nearest approach to them; and when, if there was any occasion for a notice of my opinions, a critic of 1871 should have referred to the formal expression of them in my "Manual of Geology," first published in 1863. The reader will there find the "diagenesis" of Gumbel, which Mr. Hunt takes occasion to commend, applied, as had been done by others, although Gumbel had not then announced it; and also other points discussed, with but a brief allusion to pseudomorphism.

The above remark by Mr. Hunt is not made with special reference in his address to magnesian silicates, or any other particular class of siliceous minerals; but, as the context shows, to rocks in general. I have held to views respecting the origin of serpentine which Prof. Hunt rejects, and have sustained them on the ground that the pseudomorphous crystals of serpentine show what transformations are chemically possible, and that hence they may possibly illustrate the changes which beds of rock have undergone. I have not applied this principle in accounting for the origin of ordinary metamorphic rocks, because, as above observed, crystals may often be reached by agencies which can never reach or affect rock-formations, and for various other reasons against it. But the case of serpentine has been regarded as somewhat

* Prof. Hunt's address has been published in the "American Naturalist" for September, 1871, and, since then, in part, in NATURE, Vol. v. Nos. 105, 106, 107. Prof. Dana's reply is reprinted from advance-sheets of *Silliman's Journal* forwarded to us by the author.

different; and I have believed, and still believe, that extended beds of rock have been turned into this mineral by a method analogous to that which takes place in pseudomorphism. Had Mr. Hunt's statement been made a special one, restricted to this case, I should have had little objection to it. I may add that the method of origin for serpentine which I have deemed most probable (though perhaps not the only method) is one which he once advocated—that of the alteration of beds of dolomite, or magnesian carbonate of lime, by waters containing alkaline silicates in solution; and it has appeared to me that the facts (1) that serpentine is commonly associated with beds of limestone or dolomite, (2) that chrysolite crystals are sometimes found in these rocks, and (3) that the forms of crystals of both dolomite and chrysolite occur among serpentine pseudomorphs, give strong support to this view.

Prof. Hunt's opinion on this point in 1857 he thus expressed in a letter to the writer, sent for insertion in "Siliman's Journal," where it appears in volume xliii. (1857) at p. 437, as a conclusion to his brief statement.

"Suppose a solution of alkaline silicate, which will never be wanting among sediments where feldspar exists, to be diffused through a mixture of siliceous matter and earthy carbonate, and we have, with a temperature of 212° F., and perhaps less, all the conditions necessary for the conversion of the sedimentary mass into pyroxenite, diallage, serpentine, talc, rhodonite, all of which constitute beds in our metamorphic strata. Add to the above the presence of aluminous matter, and you have the elements of chlorite, garnet, and epidote. We have here an explanation of the metamorphism of the Silurian strata of the Green Mountain range, and I believe of rock metamorphism in general." Again, in a letter dated July 6th, published in volume xxiv., at page 272, he says:

"I have already in a previous note indicated the manner in which I suppose these siliceous and argillaceous magnesites and dolomites to have been in certain parts of the formation transformed by the intervention of solutions of alkaline carbonates into silicates, such as talc, serpentine, chlorite, pyroxenite, &c. A further development of my views of the metamorphism of sediments, with the results of the investigation of a great many altered rocks, will appear in the Report of Progress of the Geological Survey of Canada for the last three years—now in press."

It should be added, that Prof. Hunt acknowledges his change of opinion in his address. But, in view of it, some moderating of his positiveness of assertion would have been reasonable.

4. That he attributes the origin of *beds* of serpentine and steatite,—here following nearly Delesse,—to the alteration of beds of different hydrous magnesian silicates related to sepiolite (meerschaum), formed in the surface waters of an era—Palæozoic or earlier—while fossiliferous rocks were in progress;—when, as a matter of fact, no such sepiolite-like beds are known to occur anywhere in *unaltered* stratified formations of Palæozoic or pre-Silurian time, and they are found of limited extent only in some strata of comparatively recent origin. The hypothesis, although deserving of consideration, is therefore without any solid foundation. The doubts that have been recently thrown about the Eozoön affect unfavourably the hypothesis, since these supposed fossils have been made prominent in its support. The view, if true, would, as Prof. Hunt implies, bring the making of serpentine and steatite rocks under the kind of metamorphism styled by Gumbel diagenesis, instead of that of epigenesis; making them a result of change without an addition of ingredients from any external source, like most other metamorphism, instead of through the agency of outside ingredients. But it wants facts to rest upon.

5. That he attributes an origin similar to that for serpentine and talc to beds of chlorite and hornblende; notwithstanding the fact that chlorite schist and horn-

blende schist—the purest forms of any large beds of these minerals—are always more or less impure, and often graduate into clay slate on one side, and mica schist on the other; and that these schists are thus so involved with others, that if one is derived from ordinary sedimentary beds, all must be.

6. That he devotes some pages to a "theory of envelopment" as a method of accounting for the silicate pseudomorphs referred to, beginning a paragraph with the sentence:—

"By far the greater number of cases on which this general theory of pseudomorphism by a slow process of alteration in minerals has been based, are, as I shall endeavour to show, examples of the phenomenon of mineral envelopment, so well studied by Delesse in his essay on Pseudomorphs."

While, in fact, this theory has almost nothing to do with the subject, since pseudomorphs of serpentine, steatite, and other species, with regard to which there is the dispute, consist often of *pure* serpentine, steatite, &c., and therefore have no enveloper, and are not cases of envelopment. This theory supposes the material of the so-called pseudomorph to be an impurity taken up into a crystal in process of formation—a thing of common occurrence; and, if satisfactory, would account for the want of conformity between internal qualities and external form. It is unfortunate for it that, as just shown, it does not apply where it is wanted.

7. That he makes Delesse the author of the "theory of envelopment":—when Delesse has not proposed any such theory for cases of ordinary pseudomorphism, but has simply commenced, and very judiciously, his work on Pseudomorphs (1859) by distinguishing the examples of mere impurity, or envelopment, in crystallisation, in order to clear the way for the actual facts; and then gives a long list of admitted pseudomorphs, including in it nearly all kinds so recognised by other authors, and all that affect the question discussed by Prof. Hunt; serpentine occurring in the list as forming pseudomorphs after chrysolite, hornblende, garnet; steatite after pyroxene, hornblende, epidote, scapolite, mica, topaz, magnesite, dolomite, &c. In his work on metamorphism (1861), Delesse takes back none of his views on pseudomorphism; and in his late "Reviews of the Progress of Geology," down to the last just out (1871), he reiterates the ordinary views with regard to pseudomorphism, and mentions the occurrence of other pseudomorphs consisting of talc, serpentine, &c.

8. That he cites Naumann as sustaining the "theory of envelopment":—when this learned crystallographer and mineralogist has only commended Delesse's chapter on the envelopment of minerals in crystals, and presents in his "Mineralogy" (the last edition of which, that of 1871, is now before me) the subject of pseudomorphism in the usual way, with nothing whatever on the theory of envelopment; and, under the description of the species serpentine, he speaks of "large pseudomorphous crystals of serpentine from Snarum which still contain a nucleus of altered chrysolite."

There is hence no foundation for Mr. Hunt's statement that his views are "ably supported by Delesse," or any occasion for the "no small pleasure" he derived from Naumann's letter; or any warrant for the remark (p. 47) that Delesse and Naumann hold the "view" "that the so-called cases of pseudomorphism, on which the theory of metamorphism by alteration has been built, are, for the most part, examples of association and envelopment, and the result of a contemporaneous and original crystallisation." These men of science are not to be counted upon for aid, countenance, or comfort; though claimed as friends, it has not been their fault, as they have always avowed the opinions of Haidinger and the "many others." It is a strange fact that, neither these claimed friends, nor the many announced opponents, with one or two exceptions,

hold the views which Prof. Hunt has attributed to them in his address. We are glad to know that this is not the usual American method of dealing with authorities.

Gümbel and Credner are the other two claimed supporters of his views. They have sustained Mr. Hunt's opinions as regards the Eozöon and the origin of the serpentine constituting it. But whether they disagree with Haidinger and all others as to pseudomorphs of serpentine, and of other hydrous silicates, I cannot say.

9. That while setting down the Taconic rocks, and rightly, as Lower Silurian in age, he denominates the micaceous gneisses, diorites, epidotic and chloritic, stætitic and serpentinous rocks, talcoid mica schists, quartzites, and clay-slates (which are always without staurolite or andalusite), in fact, the whole range of metamorphic rocks, with small exceptions, between the Connecticut river and the great limestone formation of the Green Mountains (admitted to be Lower Silurian), as the *Green Mountain Series*, and makes the whole "pre-Cambrian" in age, although the region has not been examined by any one stratigraphically with the care necessary for a positive opinion; and, although there are gneisses, mica schists, and chloritic talcoid (or mica) schists in the Taconic series, and therefore of admitted Lower Silurian origin, which are closely like those of his *Green Mountain Series*.

10. That he denominates, in like manner, the gneisses, mica schists (said to be richer in mica than those of the *Green Mountain Series*), hornblende gneisses and schists, micaceous and clay-slates containing andalusite, cyanite, or staurolite, and certain limestones, existing east of the Connecticut river, as a *White Mountain Series*, and makes these a newer "pre-Cambrian" than the *Green Mountain Series*:—when there is the same want of stratigraphical evidence as to age as in the former; and when Prof. C. H. Hitchcock's discoveries of Helderberg corals (Lower Devonian, according to Billings, or else upper beds of the Upper Silurian), at Littleton, not far north of the western extremity of the *White Mountain Series*, makes it more probable that part of the *White Mountain Series* of beds are of Helderberg age rather than pre-Silurian; and his discovery of labradorite rocks on the south-western margin of the *White Mountains*, wholly unlike any of the so-called *White Mountain Series*, shows further that a vast amount of study in the field is needed before the dictum of any one respecting the age of New Hampshire rocks is worth much.

It is now proved that there are labradorite rocks in Waterville and Albany, N.H., on the borders of the *White Mountain* region, which are *probably of Laurentian* age; that on the other side of the *White Mountain* line, but 25 miles to the north-northwest, there are fossil-bearing, metamorphic rocks of the *Helderberg* (upper or lower) period; that 100 miles south-southwest, in Bernardston, Mass., or central New England, there are other fossil-bearing metamorphic *Helderberg* rocks, some of the well-preserved crinoid stems (as the writer has seen, as well as read of in the account of Prof. Hitchcock) *an inch in diameter*. Who then knows whether all, or any, of the long intermediate periods of geological time, from the Laurentian to the Devonian, are represented in the New Hampshire metamorphic rocks lying between these limits? When observation has given positive knowledge, we may then have several "*White Mountain Series*."

11. That he has relied, for his chronological arrangement of the crystalline rocks of New England and elsewhere, largely on lithological evidence, and commends this style of evidence, when such evidence means nothing until tested by thorough stratigraphical investigation. This evidence means something, or probably so, with respect to Laurentian rocks; but it did not until the age of the rocks, in their relations to others, was first stratigraphically ascertained. It may turn out to be worth something as regards later rocks when the facts have

been carefully tested by stratigraphy. A fossil is proved, by careful observation, to be restricted to the rocks of a certain period, before it is used—and then cautiously—for identifying equivalent beds. Has anyone proved by careful observation that crystals of staurolite, cyanite, or andalusite, are restricted to rocks of a certain geological period? Assumptions and opinions, however strongly emphasised, are not proofs.

It is no objection to stratigraphical evidence that it is difficult to obtain; is very doubtful on account of the difficulties; may take scores of years in New England to reach any safe conclusions. It must be obtained, whatever labour and care it costs, before the real order and relations of the rocks can be known. Until then, lithology may give us guesses, but nothing more substantial.

Mr. Hunt's arguments with reference to the *White Mountain Series*, as urged by him in 1870, will be found in *Silliman's Journal*, ii. l. 83. Both there, and in his address, may be seen the kind of evidence with which he fortifies, or supplements, that based on the character of the rocks. Direct stratigraphical investigation over the region itself, in which all flexures, faults, and unconformabilities have been thoroughly investigated, is not among the foundations of opinion which he brings forward.

He endeavours to set aside the objections to his views suggested by the existence of Devonian or Helderberg rocks in central and northern New England; but he presents, for this purpose, only some general considerations of little weight, instead of definite facts as to the extent and variety of the metamorphic strata that are part of, because conformable to, these Helderberg beds. Had he studied up these stratigraphical relations with the care requisite to obtain the truth, and all the truth, perhaps he would no longer say—it is "contrary to my notions of the geological history of the continent to suppose that rocks of Devonian age could in that region have assumed such lithological characters." Notions often lead astray.

JAMES D. DANA

NOTES

THE Royal Horticultural Society has taken a step which may prove very advantageous to the interests of science, namely, the appointment of a botanical Professor, who, by lectures, answers to personal inquiries, and other means, shall assist in establishing a more correct knowledge of the principles of botany and horticulture, and of the names of plants, among those of the Fellows and their gardeners who are desirous to profit by the opportunity. Among the duties of the Professor of Botany will be to conduct the scientific business of the society, both horticultural and botanical; to enter into communication with horticultural and botanical establishments at home and abroad; to conduct the meetings and edit the publications of the society; to give courses of lectures on scientific botany to the gardeners and others; and to have a general superintendence of the gardens at Chiswick. The appointment to this office of Mr. W. T. Thistleton-Dyer, late Professor of Botany at the Royal College of Science, Dublin, is a guarantee that the cultivation of scientific botany will not be neglected.

DR. DAVID FERRIER has been appointed Professor of Forensic Medicine at King's College, London, *viz* W. A. Guy, M.B., resigned.

THE Secretary of State for India has appointed Mr. A. G. Greenhill, Fellow of St. John's College, Cambridge, Professor of Applied Mathematics at the Civil Engineering College, Cooper's Hill. Mr. Greenhill graduated as Second Wrangler in 1870, and was bracketed equal with the Senior Wrangler for the Smith's Prize; he also gained a Whitworth Scholarship while an undergraduate.

THE Radcliffe trustees at Oxford, anxious to aid one or more advanced students in the scientific study of preventative or curative medicine, offer 10*l.* a month, for three months, to a student of St. Bartholomew's, Guy's, or St. George's Hospitals, desirous of working for that time in Oxford. He will have opportunities of studying physics, chemistry, geology, the higher parts of biology, clinical and sanitary medicine. Candidates must be recommended on intimate personal knowledge by the Dean or secretary of their medical schools, and will not be submitted to an examination. The first election will be in the last week of February. There will be an election of another student in April.

A GENTLEMAN named Millard has bequeathed to the President and Fellows of Trinity College, Oxford, 8,000*l.* for the advancement of mathematical and general science.

THE University of St. Andrew's has conferred the degree of LL.D. on Mr. Archibald Cunningham Geikie, Professor, of Mineralogy and Geology in Edinburgh University.

THE Royal Irish Academy have granted from the fund at their disposal for scientific research, the following :—50*l.* to C. R. C. Tichborne, for Researches on the Dissociation of Salts in hot solutions, and on the History of the Terebenthes; 30*l.* to E. T. Hardman, for Chemico-Geological Researches; 25*l.* to Prof. R. S. Ball, for Researches in the Motion of Vortex Rings; 25*l.* to Prof. S. Downing, for Researches on the Motion of Water through Curved Tubes; 50*l.* to P. S. Abraham, for Biological Researches on the Coast of Madeira.

ROBERT PATTERSON, F.R.S., died at his residence, Belfast, on the 14th. He was born in April 1802. Educated at the Belfast Academy, in his early days he contemplated the Irish Bar as a profession, but finally devoted himself to mercantile pursuits. At a very early age he was an ardent student of Natural History, and in 1821 he joined with a few others to form the Natural History Society of Belfast. Among the first papers read before this Society were a series by Mr. Patterson on the insects mentioned by Shakespeare, which were afterwards published. His most important contribution to biological literature was, perhaps, his "Zoology for Schools," the first part of which appeared in 1846. This little work proved a great success. It was adopted by the Commissioners of Irish National Schools, and also by the Committee of Education in England, and most certainly gave a great impulse to the study of Zoology among the school classes of Great Britain. This led to the issue in 1853 of "Zoological Diagrams," large coloured plates which have proved of material assistance to both the teacher and the taught. He was a member of the British Association in its early days, and we believe that the daily printed "Journal of Proceedings" was an idea that originated with him. Of the different positions of honour and trust held by Mr. Patterson in his native town, we need not here speak. He was elected a member of the Royal Irish Academy in 1856, and a Fellow of the Royal Society in 1859. His genial and kindly presence will be missed by very many of his old and young friends.

Harper's Weekly notes the death of Mr. W. Harper Pease, at Honolulu, about the last of July, 1871. This gentleman was an American, born, we believe, in Pennsylvania, and was occupied for a long period in natural history pursuits. During the Mexican war he visited that country, under the protection of the American army, and made extensive collections of birds, which were deposited in the Academy of Natural Sciences at Philadelphia, among them some new species described by Mr. Cassin. About the year 1853 he visited the Sandwich Islands, and occupied himself for a time as a surveyor, and was sufficiently well pleased with the climate and country to remain there, marrying a native, and adapting himself to the customs of the people. During the

whole of his residence in Polynesia he was engaged in studying the mollusca of the Sandwich Islands, and gradually extended his research to the species of all the Polynesian group, making collections either directly or through the medium of Mr. Garrett and others. Numerous communications from his pen upon Polynesian conchology have appeared in the *Journal de Conchologie* of Paris, the *Conchological Journal* of Philadelphia, the *Proceedings* of the Zoological Society of London, and elsewhere, and he has long been recognised as a thorough naturalist and reliable author. He had accumulated around him at Honolulu a very large library of conchological works, which, indeed, lacked few if any of the more important treatises. He enriched the principal cabinets of America and Europe by furnishing extensive collections, by which means he obtained, in part, the facilities for procuring the books needed for his investigations. He was for several years in ill health, and his death by consumption was not at all unexpected by his friends.

We also learn from *Harper's Weekly* of the death in Reading, Pennsylvania, on December 26, 1871, of Mr. Charles Kessler, in the sixty-sixth year of his age. Mr. Kessler was known as an ardent and successful student of entomology, devoting himself to the lepidoptera, or butterflies, and bringing together a very large collection of insects of this order. We have not heard what disposition is to be made of this collection, but we presume it will ultimately come into the possession of some one of the natural history museums of the country.

PROF. WYVILLE THOMSON has been prevented from lecturing to his students for the past fourteen days, owing to a mild attack of continued fever. He hopes, however, to be able to begin again on Wednesday next. Dr. Christison has also been laid up for some days, owing to an attack of ephemeral fever.

We learn from the *Academy* that the African traveller and botanist, Dr. Schweinfurth, has happily returned in safety to Europe, and though he has suffered the loss of the greater part of his invaluable collections and drawings, he has brought back a harvest of information and experience which places his journey among the most successful of modern times. After his great journey west of the Upper Nile, in the country of the Niam-Niam and Monbuttu, he made a short excursion from his headquarters, the Seriba Ghatta, westward to Kurkur and Danga, positions formerly visited by Petherick, and returning, planned a much more extended journey, when a fire broke out in the Seriba Ghatta on the 2nd of December, 1870, which not only destroyed the station, but with it the whole property of the traveller. Fortunately, a portion of his collection was at that time already on its way to Berlin. Provided with a few necessities at Seriba Siber, the headquarters of the Egyptian troops, the indefatigable traveller made a tour in a part of Ferit hitherto unvisited by Europeans from December 1870 to February 1871, during which he found that the Bachr-el-Arab is unquestionably the main stream of the basin which mouths in the Nile at the Bachr-el-Ghazal. Having been deprived by the fire of every instrument by means of which any mechanical reckoning of the distances traversed during this journey could be made, the explorer, with an energy perhaps unexampled, set himself the task of counting each step taken, and in this way constructed a very satisfactory survey of his route.

Harper's Weekly announces the receipt of advices as late as the 5th of November from Mr. William H. Dall, whose return to Alaska under the auspices of the Coast Survey we have already chronicled. Mr. Dall is well known for the encyclopædic work published by him some time ago upon Alaska, the result of several years' residence in that region. His present position gives him unusual advantages for observation and research, and will doubtless be made the most of in gathering an important mass of

information. He is now stationed at Iliuliuk, in Unalaska, and engaged in surveying harbours and taking soundings, and generally in gathering such information as to the shores and their adjacent waters, the tides and currents, as will be to the interest of commerce and navigation. He is also using his opportunities in dredging for marine animals, and in making collections of natural history, of which he has already accumulated quite a number.

THE first contribution to science from the *Hasler* expedition, under Prof. Agassiz, appears in the form of a letter addressed to Prof. Peirce, dated St. Thomas, December 15. In this it is stated that, in the course of the frequent examination of the floating Gulf-weeds made daily, for the purpose of collecting the marine animals that usually inhabit them, a mass of this weed was found, the branches and leaves of which were united together by fine threads, wrapping it in every direction into the form of a ball. The threads forming the connecting material were elastic, and beaded at intervals; the beads being sometimes close together, sometimes more remote, a bunch of them occasionally hanging from the same cluster of the threads. From the accounts of the professor it would appear as if a globular mass had been formed by wrapping up a small quantity in the thread, and then adding more, and continually wrapping it up, until a ball of considerable size was produced. A careful examination of these beads showed that they were in reality the eggs contained in the substance of the threads, and in some the embryo was sufficiently far advanced to prove that they belonged to a fish. The mass was preserved and watched until some became detached and were free in the water; and by a very interesting process of critical investigation, the fish itself being too small for identification, it was ascertained, mainly through the structure of the pigment-cells, that they belonged to a small species, quite common in the Gulf Stream, known as *Chironectes pictus*. In this genus the pectoral fins are supported on arm-like appendages, giving them the power of hands; a somewhat similar structure in some allied forms enabling them, when thrown on the shore, to walk or crawl back leisurely into the water. It is somewhat remarkable that these eggs should have been found in the month of December, when the great majority of species lay their eggs in early spring. It is possible that *Chironectes pictus* may be an exception to the general rule. A scarcely less interesting peculiarity is seen in regard to the eggs of the goose-fish, or the common fishing-frog, of the Atlantic coast. This is an extremely hideous-looking species, shaped like a much-depressed tadpole, with an enormous head and huge mouth, and sometimes weighing from fifty to one hundred pounds. It is known to naturalists as *Lophius americanus*. The eggs of this species are contained in an immense flat sheet of mucus, sometimes thirty or forty feet long, and twelve to fifteen wide, which, when floating along the surface of the ocean, resembles nothing so much as a lady's brown veil. The mucus is so tenacious as to admit of being wrapped around an oar and dragged on board a vessel, but is extremely slippery, and readily escapes from one's grasp. The eggs, or embryos, are disseminated throughout this sheet at the rate of ten to twenty to the square inch, and by their brownish colour tend to give the impression just referred to. The number of eggs in one of these sheets is enormous, in some instances exceeding a million.

THE *Gardener's Chronicle* inquires whether the physicians or the lecturers on Botany at St. Thomas's Hospital and King's College Hospital, London, respectively, have been consulted as to the planting that has been lately carried on in the enclosures facing the buildings we have mentioned. We can hardly suppose that these gentlemen can have had any voice in the matter, since they must be too good physiologists not to know what must be the inevitable result of such operations. At St. Thomas's the expenditure for evergreen shrubs must have been very con-

siderable. There are scores of such things as *Libocedrus decurrens*, *Cupressus Lawsoniana*, *Thujopsis borealis*, *Willingtonia*, and the like, which are certain to die. The selection of evergreen shrubs for the Thames Embankment (north) is sufficiently unfortunate, but for reckless planting commend us to the Hospital of St. Thomas. At King's College Hospital the planting has been more modest, the victims consisting merely of cherry laurels. Surely we might have looked for a little common sense in such establishments as we have alluded to.

AT the Wisbech District Chamber of Agriculture, held on February 1st, some very interesting remarks were made by Mr. S. H. Miller, advocating the establishment of a County Agricultural Laboratory in which chemistry, botany, and agricultural meteorology might be prosecuted, in which young farmers might get a scientific training, and to which soils and manures might be sent for analysis. The warmth with which the proposal was received by those present augurs well for the manner in which subjects of this kind are now taking hold of the agricultural and commercial mind. We heartily commend the subject to the attention not only of Chambers of Agriculture, but of Chambers of Commerce throughout the country.

EQUALLY satisfactory was the reference made at the half-yearly meeting of the Scottish Meteorological Society, held on January 25th, by Mr. Milne Home and Mr. Melvin, to the extent to which this country is lagging behind in its endeavours to increase our knowledge in scientific agriculture. The following resolution was passed at the meeting:—"This meeting having had explained to it a scheme proposed by Commodore Maury, of America, for obtaining reports from all countries of the state of growing crops, and also of the weather in the districts where these crops are growing, so as to warrant correct estimates of these crops as regard both quantity and quality; and having learnt that an influential agricultural society in America has approved of the scheme, and applied to the United States Government to carry it out, and to invite the co-operation of the Governments of other countries, agree to express a general approval of the scheme, and remit to the Council to make a favourable answer to Commodore Maury's communication."

AT the recent annual *conversations* of the Sheffield Literary and Philosophical Society, the annual address was delivered by Mr. H. C. Sorby, F.R.S., as president. Among the remarkable inventions of the year he referred especially to the honour done to the town by Mr. Earnshaw's new method of integrating partial differential equations, and to the invention of the Moncrieff gun-carriage, where, by a simple application of mechanical principles, the force of the recoil is utilised, and made instrumental in protecting the men and the gun, and employed to raise it into a position for the next shot.

THE pages of the "Public Ledger Almanack" are filled with far more sensible matter than usually finds its way into similar publications. We find articles on the atmosphere, on the various descriptions of weather signals, and on the United States Coast Survey.

M. QUETELET reprints a eulogium on the late Sir John Herschel, spoken before the Academy of Science of Brussels, of which he was an associate.

MR. FAIRGREVE, the proprietor of Wombwell's No. 1 Menagerie, is retiring from business, and is going to dispose of the stock. The horses requisite for the dragging of the vans were sold the other day in Edinburgh, and realised over 1,400*l*. This sum gives a slight insight into the large capital invested by the owners of menageries. It is not known what he is going to do with the animals. There is some talk of another Zoological Garden being formed in Edinburgh, but nothing definite.

AERIAL NAVIGATION IN FRANCE*

THERE has been a most interesting sitting at the Academy of Sciences, at which M. Dupuy de Lôme read a report on his newly tried and apparently successful system for steering air balloons. M. de Lôme is one of the most eminent—if he is not the most eminent—of living French engineers. He was the first to apply steam to ships of war, and he was one of the earliest designers of ironclad frigates. The piercing of a tunnel under the English Channel is another of M. Dupuy de Lôme's long-cherished projects, and he is one of the engineers who are about to commence that gigantic enterprise. During the siege of Paris by the Prussians, M. Dupuy de Lôme offered to construct a balloon which should have steering powers of its own, and so not be totally at the mercy of the winds. That some sort of guiding power was required for the balloons which were despatched from Paris during its investment by the Germans is shown by the fact that, out of sixty balloons sent out during that period, no less than fifteen failed to carry their contents to a place of safety, some falling into the sea and several into the hands of the Prussians. After much tiresome delay, M. Dupuy de Lôme's plans were accepted by the Government of National Defence, a credit of 40,000 francs (1,600*l.*) was opened for him, and he began to construct his balloon at the Palais de l'Industrie, in the Champs Elysées. So great was the difficulty, however, in constructing an immense balloon on a totally new system, in a city completely cut off from the rest of the civilised world, that M. Dupuy de Lôme's huge machine was not ready until just four days before the capitulation. When that event took place, the balloon had to be packed up and hidden away from the prying eyes of the Germans when they partially occupied Paris. Then came the Commune, and all the disorganisation which followed. It was only after much difficulty that M. Dupuy de Lôme obtained permission to make use of the buildings of the Fort Neuf at Vincennes, whence, on the 2nd inst., he started on his trial trip. Before proceeding to quote from M. Dupuy de Lôme's most interesting report, it may be as well to say a few words as to the end which the eminent aeronaut has proposed to himself. He does not pretend to be able to make independent progress in the teeth of the wind, but only to deviate from the direct set of the wind when running before it. He does not hope ever to be able to beat to windward, but only to tack to right or left with the wind. A sailor would say that M. Dupuy de Lôme wanted to be always running free with the wind on the quarter. So if the wind set straight from Paris to Brussels, an ordinary balloon could only land at some point between Paris and Brussels, or else beyond the Belgian capital. But with a balloon constructed on M. Dupuy de Lôme's system, the aeronaut might steer his course either on the port or starboard tack, and might descend at London or Cologne, as he saw fit.

Having said this much, let me try to describe the balloon which M. Dupuy de Lôme makes use of. Let your readers imagine a gigantic egg of inflated silk, the longer axis being horizontal; to this egg is attached an oblong car, something the shape of a punt. The motive of the inventor in choosing the ovoid form was at once to obtain greater stability for the car than could be hoped for with the old balloons, and at the same time to give the least possible hold to the wind. The diameter of the balloon is about two-fifths of its horizontal length from point to point. I take the following dimensions from M. Dupuy de Lôme's highly interesting report, read before the Academy of Sciences, only changing French metres into feet for the convenience of English readers.

Total length from end to end	115 ft. 6 in.
Diameter at the point of greatest circumference	49 ft. 2 in.
Diameter of the screw	29 ft. 6 in.
Number of blades	2
Number of turns of the screw in a minute, when the balloon is going eight kilometres (five miles) an hour faster than the wind	21

M. Dupuy de Lôme thus describes the rudder by which his balloon is steered:—"The rudder is a plain triangular surface. It is made of unvarnished calico, and is kept in its place by a horizontal yard six metres long at its lower extremity. It can

turn easily on its forward extremity. The height of the rudder is five metres, and it has a superficies of fifteen metres." The car is next described—it is of wicker-work, and of sufficient size to contain comfortably the windlass for the screw, and eight men to work it; the ventilator with which to manage the small balloon—we shall have to speak of this presently—and the man who attends to it. In all, fourteen persons can be carried in the car. The driving screw is directly carried by the car. The shaft of the screw is a hollow steel tube. This shaft is constructed so as to allow of the screw being easily dismounted when a landing is effected. The rudder is fixed to the balloon itself, and the screw, as we said, is below it, and immediately attached to the car. Two blades only are used in the screw instead of four, because when the ground is touched the two blades can be placed horizontally, so as to escape injury. Were there four blades, the screw would be almost certain to be broken whenever a landing was effected. The windlass which turns the screw is worked by four, or, if necessary, eight men, in a similar manner to the steering wheel of a ship—only the wheel is placed parallel to the axis of the car, instead of at right angles to it, in order to lessen the rolling occasioned by the movements of the men working the windlass. The material of which the envelope of the balloon is composed is white silk, weighing 52 grammes, not quite 2 oz. to the square metre, and a coarser lining weighing 40 grammes the square metre, and seven coats of india-rubber, which together weigh 180 grammes, a little over 6 oz. the square metre. Thus the whole weight of the external web of the balloon is 272 grammes, about 9 oz. to the square metre. In order to render the web of the balloon totally impermeable to the hydrogen gas with which it is inflated, the silk was painted over with a sort of gelatinous compound, invented by M. Dupuy de Lôme. The total weight of the two balloons when ready to start was 570 kilogrammes, or rather more than half a ton. The web of the balloon was reckoned to be capable of supporting a pressure of over 2,000 pounds to the square yard. I have mentioned the smaller balloon; this is, more correctly speaking, only a division as it were of the larger balloon. It is formed by means of an inner skin, separating the bottom of the balloon from the rest. This compartment occupies about one-tenth of the whole cubic space of the balloon, and serves to keep it stiff, and of the required shape. By these means M. Dupuy de Lôme has attained the two ends he proposed to himself, viz., first, permanence in the shape of the balloon; and, secondly, he has been able to give the whole apparatus an axis decidedly parallel to that of the force of propulsion.

Having thus endeavoured to give some account of the new aerial navigator—no easy matter without diagrams—it only remains for us to say a few words about M. Dupuy de Lôme's first experimental trip. There was half a gale of wind blowing at the time he started, and the screw had been slightly damaged. The spirited inventor did not hesitate, however, to make his contemplated ascent. The end justified his confidence; for not only was he able to land near Noyon, in the Department of the Oise, some seventy miles north-east of Paris, but his balloon more than answered his expectations. The screw, when worked by four men, drove the balloon eight kilometres (about five miles) an hour quicker than the rate at which the wind was blowing; so that M. Dupuy de Lôme not only "went like the wind," but actually went faster than the wind. By the use of the rudder the course of the balloon could be altered eleven degrees either way from the set of the wind, making a total deviation of twenty-two degrees. This is, of course, the greatest and most noteworthy result obtained by the new aerial machine. It may possibly be asked, What is the use of the screw when the wind carries your balloon at the rate of fifty-four kilometres, or nearly forty miles an hour? The answer is, that without the screw the rudder would be of little or no use. Every one knows that a ship without any on her steering-way, as it is called, is nearly impossible to steer. And a balloon which has not, like a ship, a second element for the rudder to work on, is still more at the mercy of the wind. The next question is whether the screw cannot be turned by steam instead of by manual labour. But fire and hydrogen gas are bad neighbours, and the introduction of a steam-engine into the car—although it was hazarded some twenty years ago by one of our countrymen, Mr. Henry Giffard—would expose the aeronauts to the dangers of an explosion, followed by a descent to the earth, doubling in rapidity every sixteen feet, in accordance with the law of gravitation. Even with a steam-engine on board, there does not seem much cause to fear the "airy navies" of the inventor of ironclad ships just at present.

* Reprinted from the *Daily News*.

SOCIETIES AND ACADEMIES

LONDON

Linnean Society, February 15.—Mr. G. Bentham, F.R.S., president, in the chair.—Prof. Wyville Thomson, F.R.S., Prof. Allman, F.R.S., and Prof. W. T. Thiselton-Dyer were elected Fellows.—“On the Habits, Structure, and Relations of the Three-banded Armadillo,” by Dr. J. Murie. This animal is distinguished from the other members of the order Edentata by its habit of rolling itself into a ball like a hedgehog. The three bands act as hinges, by means of which this rolling-up is effected. It is also peculiar in walking on the points of its toes, instead of, like other armadillos, on the whole foot. It may be considered as a connecting link from the armadillo to the extinct glyptodon, and thence to the megatherium, and so on to the pachyderms.—“On a Chinese Artichoke-Gall,” by A. Müller.—“Comparative Geographical Distribution of Butterflies and Birds,” by W. F. Kirby. The total number of species of birds is stated by Dr. Sclater as 7,500, and that of butterflies is about 7,700, showing a remarkable closeness. If the surface of the globe is marked off into the divisions proposed by Dr. Sclater, we find in the Palearctic region (Northern Europe and Asia), including about 14,000,000 square miles, 630 species of butterflies and 630 of birds; in the Indian region, including Asia south of the Himalayas, about 1,200 butterflies and 1,500 birds; in the Australian region 725 butterflies and 1,000 birds; in the Nearctic or North American region, 480 butterflies and 660 birds; in the Neotropical or South American region, 4,200 butterflies and 2,250 birds; thus, in five divisions there is a preponderance of birds, which is balanced by a very large excess of butterflies in the sixth region.—An interesting discussion followed, in which Mr. A. R. Wallace, Mr. Sharpe, Mr. Stainton, and others took part, and it was shown that if Dr. Gray's estimate of the number of species of birds is taken, viz., 10,000, which is no doubt more correct than Dr. Sclater's, the apparent parallelism vanishes; that in limited districts, as the British Isles, there is no resemblance between the number of butterflies and of birds; that in Mr. Kirby's paper no reference is made to the number of birds in each region that are migratory, a most important consideration; and that the conditions of the natural features of the country, as the prevalence of forests, may be favourable to the abundance of insects, and unfavourable to that of birds.

Chemical Society, February 15.—Dr. Frankland, F.R.S., president, in the chair.—Prof. Roscoe, F.R.S., gave an account of some of his recent researches on the element tungsten, under the title “On the study of some tungsten compounds.” The author, after giving a short *résumé* of the labours of other chemists on those compounds of tungsten which he had been investigating, proceeded to describe their properties, and the methods of preparation he had employed to obtain them. As the result of his labours he has definitely settled that the metal tungsten is a monad element with the atomic weight 184, and has also showed the cause of the error of the French chemist Persoz, who assigned 153 as the atomic weight. A collection of very fine specimens of tungsten compounds was exhibited by the Professor.

Royal Geographical Society, February 12.—Sir H. C. Rawlinson, K.C.B., president, in the chair. The President announced that the expedition for the search and relief of Dr. Livingstone left England on Friday last, and was at that moment probably crossing the Bay of Discay *en route* for Zanzibar. The subscriptions from all sources, including the balance of the Government grant lying at Zanzibar, amounted to nearly 5,000*l.* Of this sum about 2,800*l.* will have been expended by the time the expedition leaves Zanzibar for the interior; the remainder would be held in reserve for contingencies very likely to occur. He read also to the meeting a letter from Earl Granville to the Sultan of Zanzibar, stating the great interest the Government and people of England took in Dr. Livingstone, and recommending the expedition organised by the Royal Geographical Society of England to his Highness's good offices; and another to Dr. Kirk, Acting Consul at Zanzibar, authorising him to apply 654*l.* of the balance of the Treasury grant of 1870, to the purposes of the expedition. So far everything connected with the expedition had been most satisfactorily and expeditiously carried out; and a message ordering the preparation of escort and porters at Zanzibar, sent as far as Aden by telegraph, would reach Zanzibar in the unprecedentedly quick space of fourteen days. Letters had been received from Dr. Kirk of so recent a date as Dec. 16, and

they informed us that no news whatever had been received since September from the interior, but that the war between the Arabs and the people of Unyamwezi would be continued. This would necessitate the adoption of an entirely new route by the expedition now on its way.—Letters were then read concerning Sir Samuel Baker's expedition. The President stated that he had received from the Prince of Wales the original letters of Sir Samuel, copies of which his Royal Highness had sent to the *Times*. A letter, three days later in date, contained the news that a fertile portion of the Bari territory beyond Gondokoro had been acquired, and that Lieut. Baker would have charge of the steamer for the navigation of Lake Albert Nyanza.—A paper was then read by Sir Harry Parkes (British Minister at Japan), entitled “Captain Blakiston's Journey round the Island of Yezo.” Sir Harry explained that his office with regard to the paper was that of reducing into readable bulk the voluminous journals which Captain Blakiston had communicated through him to the Society, and of adding some necessary explanations. Yezo was the northernmost island of Japan, larger by 3,000 square miles than Ireland, and rising in importance from its position and its great fertility and mineral wealth. Captain Blakiston, the well-known explorer of the Yang-tze-Kiang, since resident in Hakodadi in the south of Yezo, had enjoyed the peculiar advantage of travelling with the privileges of a Japanese official. He went by sea to Aki Bay, on the south-east coast, and thence by land almost entirely along the sea coast (the interior being without roads or Japanese settlements) round the island to Hakodadi. The native inhabitants are the singular isolated people called Haiyu-men, or “Ainos,” a robust race, apparently of Aryan extraction, and nearest allied to certain sections of Slavonians, distinguished by the thick growth of hair on the body, as well as head and beard.

Photographic Society, February 13.—The officers and council for the ensuing year were elected, and the accounts of the society explained by the treasurer, who reported the society free from debt and with a satisfactory balance in hand. The report of the council was read and adopted.—Dr. Anthony read a paper “On various modes of Plate-cleaning.” He stated that his experience went to show that the employment of cyanide of potassium was better than any other agent for the purpose, the plates being treated for a very brief period in the cyanide solution and then washed in water. He found mechanical methods generally rendered the bath unclean, and for this reason also deprecated the application to the glass plate of an albumen substratum. The specimens of Niepce de St. Victor were exhibited.

EDINBURGH

Royal Society, February 19.—Sir Alexander Grant, Bart., vice-president, in the chair.—1. “Remarks on Contact-Electricity,” by Sir William Thomson. 2. “On the Curves of the Genital Passage as regulating the movements of the Fœtus under the influence of the Resultant of the Forces of Parturition,” by Dr. J. Matthews Duncan. 3. “On a Method of Measuring the Explosive Power of Gaseous Combinations,” by James Dewar. 4. “Note on Modification of Sprengel's Mercurial Air-Pump,” by James Dewar. 5. Prof. Alexander Dickson exhibited a series of Abnormal Fir Cones, with remarks.

PARIS

Academy of Sciences, February 12.—MM. Delaunay and Serret protested against the insertion in the *Comptes Rendus* of a note by M. Renou relating to asserted inaccuracies in the publications of the Paris Observatory.—The controversy on fermentation and heterogeny was continued by M. Pasteur reading a reply to M. Fremy, and M. Chevreul a communication on the history of ferments after Van Helmont. M. Engel also presented a morphological investigation of the various kinds of alcoholic ferments, which he describes as forming two genera, *Saccharomyces* (Meyen) with seven species, and *Carpomyces* (*gen. nov.*) with one species. The characters of these forms were illustrated with outline figures.—M. Bertrand presented the solution of an arithmetical question by M. Bougaev; M. Serret a note by M. E. Combesure on some points in the inverse differential calculus; and a note by M. A. Mannheim on the determination of the geometrical connection which exists between the elements of the curvature of the surface of the principal centres of curvature of a given surface.—M. de Saint-Venant presented an elaborate report upon a memoir by M. Kleitz, entitled, “Researches upon the molecular forces in liquids in motion, and their application to hydrodynamics.”—M. de Pambour read a note on the theory of hydraulic

wheels, relating to the reaction-wheel.—M. Saint-Venant communicated a note by M. Boussinesq on the equation of the partial derivatives of the velocities in a homogeneous and ductile solid undergoing deformation parallel to a plane.—M. Serret presented a note by M. de Tastes in reply to a recent note by M. Ciotti on the employment of vibrating elastic plates as a means of propulsion. M. de Tastes stated that the elastic plate propeller is his invention, communicated by him to M. E. Ciotti.—M. E. Dubois presented a reply to M. Ledieu's objections to the employment of the marine gyroscope.—M. Delaunay presented a note by M. C. Wolf on the reflecting power of mirrors of silvered glass, and their application to astronomical purposes.—A note by M. D. Genex on the absorption-bands produced in the spectrum by solutions of hyponitrous, hypochlorous, and chlorous acids, was communicated by M. H. Sainte-Claire Deville.—A note by M. Baudrimont on the recent experiments of M. Poëy with regard to the influence of violet light upon vegetation was read, in which the author stated that he had arrived at totally different results, having found that violet light was fatal to vegetation.—A great number of communications from all parts of France, and also from Belgium, Switzerland, and Algeria, relating to the aurora of February 4, were laid before the Academy; they included notices of magnetic disturbances observed in the telegraphic lines.—M. Delaunay presented a paper by M. E. Stephan containing a list of nebulae discovered and observed at the Observatory of Marseilles.—M. E. Viecare read a reply to Father Secchi's observations on the temperature of the solar surface.—Some remarks were read by M. Harting on the saccharine matter observed by M. Boussingault on lime trees, which he ascribed to the action of aphides in accordance with the commonly received opinion. He stated that the saccharine secretion produced by those insects consists in great part of cane sugar. M. Boussingault in reply said that in the case observed by him the saccharine exudation appeared before the aphides, and that it contained cane-sugar, grape-sugar, and dextrine.—M. Le Verrier also read an extract of a letter from M. Folie on this subject.—M. Bussy presented a report upon a memoir by M. Louvel, describing a process for preserving grain *in vacuo*. The author suggested storing grain in air-tight granaries, in which a partial vacuum may be produced by a powerful air pump; he described the construction of the apparatus, and stated that a granary such as he proposed of the capacity of ten cubic metres (about 370 cubic feet) and containing 100 hectolitres of wheat would cost 750 francs. He stated that by this process the ravages of insects are effectually stopped.

SCIENCE STATIONS

WE shall not be far wrong, we imagine, in supposing that the article by Dr. Dohrn in a recent number of NATURE on "Zoological Stations" has attracted considerable attention among thoughtful men. We may, indeed, congratulate zoologists that so important a task has been taken in hand by one in every way so well fitted to accomplish it; and it will gratify our readers to learn that the cheery energy and bright enthusiasm of the German anatomist is fast overcoming the obstacles which his scheme naturally met with in the indolent city of the South, whose lands are so rich in classic ruins, and seas so full of Darwin-speaking embryos. At the risk of spoiling a good work we venture to add to his remarks some further suggestions, confining ourselves, however, to one or two points.

In the first place, we will be bold enough to express the doubt whether it will be advisable to separate so entirely, as Dr. Dohrn recommends, the stations in England from the work of teaching. The establishment of such stations will be rendered infinitely easier if they can in any way be made self-supporting. Dr. Dohrn hopes, if we understand him rightly, to pay the expenses of the Naples station out of the fees of the Gentile sightseers, who will be allowed to stroll about in the outer court of his embryological temple. There can be no such hope for any like English temple. Yet a very considerable share of the necessary funds might without difficulty be raised, and a Philistine British public might be made to believe that it was getting its money's worth for its money, if the work of teaching, which is palpable, which may be measured and valued, and for which a receipt in full may be given, were to go on hand in hand with the immeasurable and invaluable work of original inquiry. There would thus naturally grow up around the station a school of sound zoology; or otherwise there would be great danger of its becoming a resort of ambitious *privat-docents* anxious chiefly to find a notochord where nobody had found it before, or a home of some narrow zoological clique.

Much might be said for the establishment somewhere on our British coasts of such a school of zoology on the theory of a geographical distribution of scholarship, and the existence of particular habitats best suited for particular branches of learning. Sufficient foundations for such a theory are at hand. It is easy to understand why Edinburgh, with her sea close by, has raised so many brilliant zoologists. We can see why Manchester in the past and in the present has done so much for chemistry. And, to look at the matter from another point of view, one gets a glimpse of the reason why high mathematics flourish at Cambridge, when one gazes at her fenny flats, where, if the conception of three dimensions be once reached, that of four is soon gained, and feels the fogs and mists which wash out of the mind everything that is not held fast by formulæ. The natural habitat for an English school of zoology is surely some bright spot on our southern coast.

Nor need such an institution necessarily have an in-

dependent isolated existence. There is too great a want of community in our English Universities and Colleges especially in matters of natural science. There is one zoology at Oxford, another at Cambridge, another at Jermyn Street, and these three have miserably little dealings with one another. What immeasurable good would a place of higher teaching do, where for a season, or for a term, the zoological students of all the Universities might mingle together with mutual diffusion of ideas! * The mere opportunity of material would be a great thing: the Cambridge student would lift his ideas above the line of beautifully prepared vertebrate skeletons, the Oxford man would benefit by the change of diet from Anodon and Astacus, and the London man would learn to see actual things instead of reading about them in books. But the greatest thing of all would be the catholic enthusiasm for biological learning, which such an institution could not fail to generate and foster.

Another remark which we would wish to make takes on somewhat the shape of a complaint against Dr. Dohrn, that he has confined to one science ideas which should properly belong to all the sciences of observation. It is well to have a Biological station, but it is far better to have a station at once Biological, Astronomical, and Meteorological. Let us imitate Dr. Dohrn in giving our views a concrete form. The eclipse party on their outward, and even on their homeward voyage, cannot fail to have been struck with the bright clear air of the North Red Sea. There is the very land of observation. It is impossible for any one with a fragment of a mind within him to sojourn on those delightful shores, where the eye rejoices in its power, where the air helps vision instead of hindering it, where the water is as clear and transparent as the air elsewhere, without the desire springing up to be a naturalist by day and an astronomer by night. And this blessed region is now little better than a week's journey from the fogs of London. Nothing could be easier than to establish at no great expense a Science Station at some spot on the shores of the Red Sea, a little south of Suez. Suez itself is for many reasons undesirable, but the little village of Tor suggests itself as being a very suitable neighbourhood. There would be comparatively little difficulty in getting supplies, or in going and coming to and fro. The naturalist, the astronomer, the meteorologist, with the Palestine explorer as an occasional helpmeet, might spend here a winter, or rather many winters, in which pleasure and profit would be running a hard race together.

We cannot help thinking that such an idea has only to be mooted to be at once caught up and set in action. The outlay of the initial building and arrangements need not be heavy, while the yearly expenditure might be kept within comparatively narrow limits. Such an undertaking is one which Government might justly take in hand, but it is also one which private liberality might largely aid, and to which contributions might come from the funds of our ancient seats of learning. In any case we fairly think it is matter deserving serious attention, and as such we leave it to our readers.

* It is impossible in a short article to develop a complete scheme; we might indicate our ideas, however, by suggesting that the right to study for one or more terms in the station might be granted as a sort of scholarship to promising biological students selected from all our great teaching institutions.

BURTON'S ZANZIBAR

Zanzibar: City, Island, and Coast. By Richard F. Burton. In 2 vols. (London: J. Murray, 1872.)

IN these two bulky volumes Captain Burton gives us, after a lapse of thirteen to sixteen years, a narrative of his adventures and explorations in the island of Zanzibar, the neighbouring smaller islands, the adjacent coast of the mainland, and the Highlands of Eastern Africa intervening between the coast and the great Victoria N'yanza, the publication having been delayed by a series of remarkable accidents. As in everything else that Captain Burton has written, the volumes are full of graphic delineations of the natural features and inhabitants of the country, combined with not a few details of a personal character which have not the same interest for the general reader.

In 1856 Captain Burton laid before the Royal Geographical Society his desire once more to explore Equatorial Africa; a committee was formed to assist him in his undertaking, a grant of 1,000*l.* was obtained from Lord Clarendon, then Secretary of State for Foreign Affairs, and on September 16th the enterprising traveller received formal permission, "in compliance with the request of the Royal Geographical Society, to be absent from duty as a regimental officer under the patronage of Her Majesty's Government, to be despatched into Equatorial Africa, for a period not exceeding two years, calculated from the date of departure from Bombay, upon the pay and allowances of his rank." On December 26th in that year he landed at Zanzibar, the first view of which is thus attractively described:—

"Earth, sea, and sky, all seemed wrapped in a soft and sensuous repose, in the tranquil life of the Lotos-ethers, in the swoon-like slumber of the Seven Sleepers, in the dreams of the Castle of Indolence. The sea of purest sapphire, which had not parted with its blue rays to the atmosphere—a frequent appearance near the equator—lay basking, lazy as the tropical man, under a blaze of sunshine which touched every object with a dull burnish of gold. The wave had hardly energy enough to dandle us, or to cream with snowy foam the yellow sandstrip which separated it from the underwood of dark metallic green. The breath of the ocean would hardly take the trouble to ruffle the fronds of the palm, which sprang like a living column, graceful and luxuriant, high above its subject growths. The bell-shaped convolvulus (*Ipomœa maritima*), supported by its juicy bed of greenery, had opened its pink eyes to the light of day, but was languidly closing them, as though gazing on the face of heaven were too much exertion. The island itself seemed over-indolent and unwilling to rise; it showed no trace of mountain or crag, but all was voluptuous with gentle swellings, with the rounded contours of the girl-negress, and the browned tinge of its warm skin showed through its gauzy attire of green. And over all bent lovingly a dome of glowing azure, reflecting its splendours upon the nether world, whilst every feature was hazy and mellow, as if viewed through 'woven air,' and not through vulgar atmosphere."

A residence, however, of some months in the island by no means established the impression which its first appearance might convey, of its being a terrestrial paradise. The city of Zanzibar itself is a miserable, ill-built place, fœtid and unhealthy; while the personal appearance and habits of the natives are repulsive in the extreme. The climate is remarkably uniform as to temperature, the result of nine months' observation showing a range of

18°—19° F. only. The medium temperature of January is 83°5'; of February, the hottest month in the year, about 85°; and the mean gradually declines till July, the coolest month, 77°. The mean average of the year is between 79° and 80°. The barometer is almost uniformly sluggish and quiescent, a few tenths above or below 30 in. representing the maximum variation, even under the influence of a tornado. Uniform, however, as is the temperature, the degree of humidity of the atmosphere varies excessively. At certain seasons the amount of moisture exceeds that of the dampest parts of India, and the annual rain-fall is in some years double that of Bombay, varying from 100 to 167 inches. The Msika, or principal rainy season, lasts from April to June; the island is enveloped in a blue mist, and the interior becomes a hot-bed of disease; the hair and skin are dank and sodden; shoes exposed to the air soon fall to pieces; paper runs and furniture sweats; the houses leak; books and papers are pasted together; ink is covered with green fur; linens and cottons grow mouldy; and broadcloths stiffen and become boardy. This excess of damp is occasionally varied by the extreme of dryness. During the prevalence of the dry wind cotton cloth feels hard and crisp, books and papers curl up and crack, and even the water is cooled by the excessive evaporation. Earthquakes are all but unknown in Zanzibar, a single shock being recorded as having been felt in 1846. Tornadoes are frequent, but the cyclones and hurricanes of the East Indian islands rarely extend to this coast. During fourteen years there was but one tourbillon strong enough to uproot a cocoa-nut tree.

The prosperity of Zanzibar depends almost entirely on its vegetable productions, and chiefly on the cocoa-nut and the clove. The former supplies the natives with nearly all their wants—food, wine, spirit, cords, mats, strainers, tinder, firewood, timber for houses and palings, boats and sails; and Captain Burton calculates that in 1856 12,000,000 nuts were exported for the soap and candle trades. The sugar-cane might be grown to great advantage, but for the constitutional indolence of the inhabitants. Cotton has been tried, but does not thrive; and coffee has not been cultivated to any extent. The fruits in greatest request by the islanders are the mango, the orange, the banana or plantain, the pine-apple, and the bread-fruit—all, however, with the exception of the banana and an inferior kind of orange, being introduced exotics; the pine-apple has become perfectly naturalised. The most important production of the island is the clove, which does not, however, produce crops comparable to those of the East Indies either in quantity or quality, owing to want of skill and intelligence in its cultivation. The copal of commerce is obtained chiefly from the neighbourhood of Saadani, on the opposite coast of the mainland; and Captain Burton entirely confirms the account of its production already communicated to the Linnean Society by Dr. Kirk, that it is a gum, or resin, exuding from wounds in the stem of a small tree or large shrub (*Hymenoclea verrucosa*) belonging to the order Leguminosæ.

Captain Burton's first expedition from Zanzibar was to the smaller island of Pemba, lying to the north, and thence to Mombasah, on the coast 4° south of the line, the capital of Northern Zanzibar, the best harbour on the Zanzibar coast, land-locked by coral islands. The town itself is built on the largest of these islands, where the climate is

hotter, drier, and healthier than that of Zanzibar. Here he did not attempt to strike inland, the weather and the hostility of the native tribes being unfavourable, but returned along the coast southwards to Pangani, and thence inland to Fuga, the capital "city" of Usambara, in the Highlands of Eastern Africa. In order to gain a complete knowledge of the Zanzibar coast, he also paid a visit to the island and port of Kilwa, situated beneath the ninth degree of south latitude. Here are the remains of an ancient town of considerable size, with respect to which many legends are current among the natives; but the gradual sinking of the coast has rendered the ancient site uninhabitable. Although at the present time a miserable and fetid collection of squalid huts, Kilwa was found in 1500 by the Portuguese a town of great prosperity, the capital of Southern Zanzibar, and ruling the coast as far as Mozambique and Sofala; but the curses of European wars and the slave-trade have desolated the once thriving country. Captain Burton does not think very highly of the so-called "free labour" system, which he terms "the latest and most civilised form of slavery in East and West Africa."

The most important expedition made by Captain Burton was, however, that undertaken between 1857 and 1859 to Kazeih in the Ukimbu district, upwards of 500 miles from the coast, and about 2° south of the southern shore of the great Victoria N'yanza, in company with Captain Speke. But as this journey has already been illustrated in his own "Lake Regions of Central Africa," and the country has been further described by Colonel Grant and Captain Speke, he does not again enter into details respecting it; but thus sums up what he considers its geographical results:—"That the Boringo is a lake distinct from the 'Victoria N'yanza' with a northern effluent the Nyarus, and therefore it is fresh water; that the N'yanza, Ukara, Ukerewe, Garawa, or Bahari y a Pili, is a long narrow formation, perhaps thirty miles broad, and 240 miles in circumference, and possibly drained to the Nile by a navigable channel; that the N'yanza is a water, possibly a swamp, but evidently distinct from the two mentioned above, flooding the lands to the south, showing no signs of depth, and swelling during the low season of the Nile, and *vice versa*; and that the northern and north-western portions of the so-called 'Victoria N'yanza' must be divided into three independent broads or lakes, one of them marshy, reed-margined, and probably shallow, in order to account for the three effluents within a little more than sixty miles."

The botanical results of this journey are about to be illustrated by Colonel Grant, in a magnificent volume, to be published by the Linnean Society, which it is understood will be illustrated by 600 plates, the cost of which will be defrayed entirely by the gallant author.

One chapter is devoted to a sketch of the labours of Captain Burton's old comrade, Captain Speke. Though tribute is here paid to his many excellent qualities, we regret to be again introduced to the details of the estrangement which grew up between the explorers, culminating at the meeting of the British Association at Bath, when the two companions in arms met as strangers, advocates of two rival "Nile-theories," as to the origin of the Father of rivers.

In the Appendices, Captain Burton gives some useful

details of the meteorology, commerce, &c., of Zanzibar. A well-executed map helps to illustrate the author's journeys, without a constant reference to which the narrative is by no means clear; but we cannot commend the style in which the woodcuts interspersed here and there are executed.

OUR BOOK SHELF

Deschanel's Natural Philosophy. By Prof. Everett. Part III., Electricity and Magnetism. (London and Edinburgh: Blackie and Son.)

IN the Preface by the translator of the present volume, it is said, with much truth, that "the accurate method of treating electrical subjects, which has been established in this country by Sir W. Thomson and his coadjutors, has not yet been adopted in France; and some of Faraday's electromagnetic work appears still to be very imperfectly appreciated by French writers." Accordingly we find that the translator has added a considerable amount of matter, and more especially two important chapters, one on the electrical potential and lines of electric force, and the other on electrometers, together with an appendix on electrical and magnetic units. Dr. Everett has thus considerably improved a book, which, in its original form, was already a good one. The ordinary branches of the subject are unfolded, the plates are good, and the explanations are full and clear. The portion devoted to magnetism is in this, as apparently in all such general treatises on natural philosophy, considerably the most defective part, and especially in the sections which relate to terrestrial magnetism. The whole of that question is most insufficiently dealt with. The treatment of the secular changes in the magnetic elements is confined to twelve lines, where it is said that "declination and dip vary greatly, not only from place to place, but from time to time;" but from which we should expect that the unlearned reader would be led into the error that intensity is uniform. Then, again, the vast subject of changes in the elements, such as are not secular, is confined to one short paragraph, headed "Magnetic Storms"! The intrinsic importance of the subject of terrestrial magnetism, and the great and increasing interest attaching to it, no less than the extreme beauty of many of its investigations and results, entitle it to a much larger notice than the very imperfect one in this volume. The chapter on the Telegraph contains useful matter, and especially a description of an autographic telegraph, an instrument which, while interesting and ingenious, has not often found its way into such treatises. We miss such points as how to find the locality of a fault in a telegraph wire, which we might the more expect to see treated of when we consider the full explanation which is given of Ohm's laws, and when we see such elaborate details as to some telegraphic instruments as are entered into in the chapter in question. The chapters on the heating effects of currents, and on electrolysis, are clear. The question of electromotive force, and of the means of determining it, might have been entered into more fully; and, generally, from the character of the chapter on the potential, we might have expected to see a little more introduced concerning points which may be elucidated by the application of the principle of the conservation of energy.

JAMES STUART

Medizinische Jahrbücher, herausgegeben von der k. k. Gesellschaft der Ärzte, redigirt von S. Stricker. Jahrgang 1871. Heft iv. Mit 4 Holzschnitten. (Wien: 1871.)

THIS part, which concludes the first volume of Stricker's Jahrbuch, contains: (1) Researches on the Inorganic Constituents of the Blood, by Adolph Jarisch. Jarisch gives the details of an improved method by which blood can be

collected from the vessels of a dog without the loss of any of the water by evaporation, whilst at the same time, being frozen, it loses its disposition to coagulate, and when subsequently thawed can be readily manipulated. The mean of four analyses gave the following results:—

Phosphoric acid anhydride	0.1103
Sulphuric acid anhydride	0.0358
Chlorine	0.2805
Potash	0.0342
Soda	0.3748
Lime	0.0112
Magnesia	0.0058
Oxide of iron	0.0948
Total ash found	0.8922
Calculated	0.8640

In Verdeil's treatise, the amount of ashes of fresh blood is stated to be on the average 6.45 per cent. Jarisch points out that this must be an error of the press, his own results giving only 0.864 per cent., a difference that is too great to be regarded as an error of analysis. 2. An essay on the Centres of Vascular Nerves, by Dr. Soboroff. In this paper Dr. Soboroff shows from the results of experiments performed on frogs that the nerves supplying the vessels of the web of the foot proceed from the spinal cord, and run into the sciatic nerve. 3. On the presence of Fungi in the Blood of Healthy Men, by Adolph Lorstorfer. Lorstorfer drew blood from the fingers of eleven people who considered themselves in perfect health with every precaution to avoid contamination with dirt, and examined the specimens daily with a Hartnack microscope, ocular 3, objective 10. During the first two days he observed nothing remarkable, except in some cases a few scattered groups of small granules. On the third day similar groups were always found, though still scattered. The granules were of equal size, considerably larger than those of the colourless blood corpuscles, but without any definite arrangement. On the fourth day they had increased in size, and were arranged in groups of four, so as to resemble the well-known *Sarcina ventriculi*. On the fifth day the granules had slightly increased in number and size, but after this date no change was observable up to the tenth day, when the preparations became unserviceable. Lorstorfer thinks his experiments render it probable that the germs of *Sarcina ventriculi* exist in the blood as a natural condition. There are three other papers, but they are all of a purely professional nature. One being by Hofmoll on Resection of the Upper and Lower Jaw: one by Bresslau on Typhus: and one by Popoff on Pneumonia.

H. P.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

Development of Barometric Depressions

I HAVE only just had my attention called to the critique on "The Laws of the Winds prevailing in Western Europe," in NATURE of Jan. 11, which I have seen to-day for the first time. Though it is now rather late to do so, I may perhaps be permitted to point out some unintentional misrepresentations of my views into which the writer appears to me to have fallen.

He considers it improbable in the extreme that the course of baric depressions should be regulated "by one law" in intra-tropical, and by "a totally distinct law" in extra-tropical regions of the globe. I pointed out (pp. 40, 41) that in temperate latitudes the general distribution of atmospheric pressure commonly tends to transfer local depressions in an eastward direction; while the influence of precipitation resulting from the mean distribution of solar heat propagates them in the same direction. Since the reversal of pressure-distribution which accompanies polar periods only retards the eastward progression, I drew the

conclusion that, in temperate latitudes, the most important of the two factors of the progression is the influence of precipitation, and accordingly I devoted the first part of my work to this, with the promise (which I hope shortly to redeem) that the motive effect of the general pressure-distribution shall be described in Part II. All this your reviewer ignores. Had I been engaged in a discussion of the tropical cyclones, I should have proceeded in an inverse order; since the most important factor of their westward progression appears to be the mechanical influence of the distribution of surrounding pressures. It is, however, important to observe that as in temperate, so in tropical latitudes, these two influences are commonly coincident in direction. In the West Indies, e.g.—at those periods when cyclones prevail—mean temperatures are lower on the south, or left, than on the north, or right, of their course; and a similar remark applies, *mutatis mutandis*, to the typhoons of the Indian and China seas.

Briefly, my position is this. The influence of the general distribution of temperatures, and that of the general distribution of pressures, may be practically regarded as two forces, A and B, from which the progression of local depressions results. Both of these commonly act in the same direction—in temperate latitudes producing eastward, and in tropical westward, progression. But of these A is the preponderating influence in temperate, B in tropical latitudes; partly because the influence of precipitation on the surface-currents increases with diminution of temperature, and partly because the currents resulting from the general distribution of pressures are far more constant and of vastly greater extent, in proportion to the extent of the cyclones, in tropical than in temperate latitudes. I am convinced that the attempt to simplify the rules which regulate the progression of depressions by striking out either of these factors, or by the substitution of J. K. L.'s single law, will meet, as it has hitherto met, with failure.

Your reviewer also ignores what I have said (pp. 28, 29) as to the occurrence of heavy precipitations unproductive of baric depression, and thinks it necessary to travel to Khasia or to the Himalayas to find illustrations of a truth which was never intended to deny. Every one conversant, as he considers me to be, with the meteorology of Western Europe alone, is aware that heavy and extensive precipitation not uncommonly occurs without producing retrograde circulation (and sometimes with generally increasing pressures), where antecedent atmospheric conditions do not favour such developments. The reviewer concedes that the immense precipitation in the Himalayas "probably causes a very great barometric depression;" a concession which is not to be accepted, both because such a reference to antecedent probabilities is inapplicable to empirical science, and because the fact itself may be denied. But supposing this great Himalayan depression to exist, and no retrograde circulation (as J. K. L. maintains) to be developed around it, his discovery of a region in which "Ballot's rules" are contravened, is indeed one of no small importance.

Into the wide question of the influence of the earth's rotation I will not here enter, further than to remark that the hitherto admitted universality of the rules connecting the direction of all atmospheric currents with the distribution of surrounding pressures, and the variation of these rules in the two hemispheres, appears to have been satisfactorily accounted for by attributing it to the earth's rotation; while it has never been, with much plausibility, traced to any other cause or combination of causes.

W. CLEMENT LEY

Zoological Nomenclature

IN the President's address to the Entomological Society of London recently given by Mr. Wallace, one of the points most fully discussed is the rules of zoological nomenclature. These rules are undoubtedly of very considerable, though indirect, importance to science, and it is not very satisfactory to find that great divergence of opinion as to what these rules are, or should be, still prevails amongst recent describers and cataloguers.

Some years ago I was entrusted by the Entomological Society with the task of preparing a synonymical catalogue of the Coleoptera of our islands, to be published under the auspices of the Society; my attention, therefore, has necessarily been directed to the questions under discussion in this matter, and I will here state the conclusions to which I have come.

Ist. That a committee to frame and publish laws on zoological nomenclature is not to be desired. Such committee would have

no power whatever to enforce the laws it might make, and could not be expected to put an end to discussion on these points. The knot must be untied, not cut.

2nd. That the binomial system of nomenclature should not be arbitrarily considered to have commenced at any given date; but that recognisable names in all works in which this system is methodically employed should be used according to the rule of priority.

3rd. That it is not necessary to suppress a generic name in zoology because it has been previously used in botany (or *vice versa*); but that it is much to be regretted that any generic name should thus be in double use, and it should always be made matter of reproach to an author that he has committed an act of this nature.

4th. That names must be Latin to the extent that renders them capable of being written or used in scientific Latin; but that classical emendations beyond this are entirely inadmissible; no line except this can be drawn between emendation, alteration, and total suppression. The laws of classical languages have, *per se*, no more right over scientific nomenclature than has the Hindoo language. As regards the much talked-of "Amphionycha know-nothing," it should be latinised in the simplest manner, as *Amphionycha know-nothingia*; and I would further suggest that its barbarian author be well hissed whenever he ventures to show his face in a scientific assembly.

5th. That as regards placing an author's name after a species, the name so placed should always be that of the first describer of the species; nor because he has any right in the matter, but as an additional means of certainty, and as a security against change.

6th. That the specific name is the name of an object, and therefore a noun, and should be changed in gender, or any other manner, when removed from one genus to another.

7th. That it is very undesirable to use the same specific name in two closely-allied genera; but that where this has been done already no alteration should be made till the two names actually come into collision on account of the two genera being united as one genus. Surely to act otherwise is like cutting one's throat for fear somebody else should do it.

8th. That as regards placing an author's name after a genus, the name so placed should be that of the author who established the genus in the sense in which it is actually used. *Carabus* of Linnaeus included all the insects now comprised in the family *Carabidae*, at present divided into several hundreds of genera. To write, therefore, *Carabus* Linn., when we mean something entirely different, may be usual but is not desirable.

I may add, that I consider it useless to expect a perfectly stable zoological nomenclature, until zoology itself is complete and perfect; but that in order to reduce changes to a minimum, classical and other secondary claims must not be allowed any great importance.

Deep-Sea Soundings

IN reference to the very interesting article in NATURE for February 22, "American Deep-Sea Soundings," may I be permitted to make the following remarks:—It is there stated that the water-collecting cylinder is apt to lead to incorrect conclusions in regard to the gaseous ingredients of sea water obtained by its means from great depths, owing to the escape of a portion of the gases when the pressure is relieved by the cylinder being drawn to the surface. As a member of the *Porcupine* expeditions of 1869 and 1870, I had nearly eight weeks' constant daily experience in the examination of samples of abyssal water thus obtained, and I believe that I was the first to adapt the gas analysis apparatus of the late Prof. W. A. Miller to the exigencies of a laboratory on board ship. The general result of these experiments for 1869 will be found as an appendix in No. 121 of the Proceedings of the Royal Society. My object in writing now is to point out that if there were such an escape of gaseous ingredients as is indicated above, the abyssal water would be so saturated with them at the ordinary atmospheric pressure (*i.e.* after the sample was removed from the water cylinder in the laboratory), that the least elevation of temperature would be sufficient to cause a further quantity to be given off. This, however, never was the case, since I invariably noticed that there was no appearance of bubbles of gas, until the water had

been heated above 120° Fahr., and frequently still hotter. I may add that the only samples of water which appeared saturated with gaseous ingredients were those taken at the surface, after several hours of strong wind. I must confess that after giving a good deal of thought to the subject, and conversing with friends whose knowledge of physics is far greater than mine, who agree with my view of the matter, I am unable to see any reason why we should expect to find any greater quantity of gaseous ingredients in abyssal than in surface water. No doubt, if the excess were there the enormous pressure would retain it, but where is the source of the supply of the supposed excess? I have never seen a satisfactory answer to this question. The solvent is exposed to excessive pressure, but the gases to be dissolved in it are not, unless there is any evolution of gas at those depths. It is probable that this abyssal water was at some point in its circulation near the surface, when an interchange would take place between some of its dissolved carbonic acid and the oxygen of the atmosphere. And it appears to me that it is only when the particles of sea water are near the surface, and exposed to no excess of pressure, that they dissolve their gaseous ingredients, which are afterwards modified in their composition by the animal life on the sea bottom. WILLIAM LANT CARPENTER

Clifton, Bristol, February 26

Snow at the Mouth of a Fiery Furnace

It would be interesting to ascertain the temperature of the salatory drops noticed by Mr. H. W. Preece. Sudden and excessive evaporation may have produced actual congelation.

HENRY H. HIGGINS

ON THE SPECTRUM OF THE ATMOSPHERE

DURING the voyage out to India of the Eclipse Expedition, I took every opportunity of observing carefully the spectrum given at sunrise, compared with that at sun-high, and obtained the following results, which, though poor in themselves, will show the wide field open for further research.

When leaving England, and for some way into the Mediterranean, the length of the spectrum as seen at sunrise extended generally from about B in the red to near G in the violet. Great differences were, however, presented in the absorption-lines according to the state of the weather, or perhaps rather according to the state of the sky when the sun rose.

If the sun rose among yellow tinted clouds, the absorption bands about B, C, between C and D, and near D, were exceedingly well defined; at the same time the blue end did not extend so far as usual, showing that there was more absorption of the blue, while probably the greater quantity of aqueous vapour in the air reflected the red and yellow rays. In these cases the tint of the clouds generally changed to a rosy red shortly after sunrise.

A clear sunrise, on the contrary, showed an extension of the violet end, whilst the aqueous bands at B, C, and D were less defined, as if the red and yellow light were not so strong to show them out by contrast.

On passing through the Suez Canal and down the Red Sea the spectrum was shortened at both ends, leaving from little beyond C to a third from F to G; this would seem to show a general absorption going on in the atmosphere from some cause, probably light dust in the air. This idea is strengthened by the beautiful purple colour of the distant mountains, as if, though the violet rays were greatly absorbed, the red rays were so to a less degree, whilst the want of aqueous vapour allowed nearly all the yellow rays to be transmitted.

When clear of the Red Sea in the Indian Ocean, the blue became greatly reduced, and the red end extended to A; the aqueous bands were very strong indeed, so much so that on two mornings D₁ and D₂ could hardly

be distinguished amid the black mass that surrounded them; the lines near C and C' or γ of Brewster were sharp and clear.

On nearing India another change took place; the blue continued to be absorbed, till at sunrise the spectrum could hardly be seen beyond F, but the blue green became very bright, and the dark bands between δ and F very distinct, the lines commencing at 1825 Kirchhoff especially attracted notice, standing out sharp and distinct, so as at first to be mistaken for F; those nearer F at 1890 K showed as a clear broad band, but not nearly so black as 1825. I am not prepared to give an explanation of this phenomenon, but will remark that when the sun rose clear and free from clouds the aqueous bands to D were less distinct, while the atmospheric bands from D to E were clear and sharp, and those beyond δ remarkably so. But if the sun rose among clouds, these were generally tinted with a golden yellow, changing afterwards to a rose or red colour, and, as might be expected, the lines from B to D and just beyond D, were well defined, whilst from E to near F the spectrum was not so clear.

After this the duties of preparing the instruments for the eclipse prevented my taking any observations, as most of our work was done in the early morning. But after the eclipse, whilst on the Neigherry Hills, 6,000 feet above the sea, I had an opportunity of finding that the strong line at 1825 had nearly faded away. The weather was then fine, but misty. A few days after, on going down the Ghauts to Bombay, I was struck with the blue colour of the mist that was hanging about the valleys, and I examined it with the spectroscope; the blue extended much farther than usual, and the lines between δ and F were again distinct.

On the passage home the same results were obtained as on going out; but as I had a much smaller spectroscope I could not make the observations with the same accuracy as before. When passing up the Red Sea the absorption was evident at both ends of the spectrum, and the mountains were of the same beautiful purple colour that I had noticed before.

From Alexandria to Southampton we had very bad weather, constant gales, making it difficult to observe. But I got the following results: With a cloudy sky at sunrise, and appearance of wet weather, the bands from B to beyond D (δ of Brewster) were strong, whilst the blue end of the spectrum was greatly absorbed, and the lines from δ to F were less distinct; this was reversed with clear weather. As we gained higher latitudes, the blue end of the spectrum lengthened out, and the bands beyond F, particularly about 2330 K, became distinct, while the bands 1825 K and 1890 K gradually faded, and now their intensity is not one-fourth of what I observed it in the Indian Ocean.

These observations are very imperfect, but I hope, if I can get the instruments, to carry out a more perfect system of observation, feeling sure that it is a subject worthy of great consideration in meteorology, especially when taken in connection with the temperature and pressure of the atmosphere and the state of the weather.

Shanklin, Feb. 5

J. P. MACLEAR

PROF. AGASSIZ'S EXPEDITION

IT is probable that I may have been anticipated, as regards part of the present communication. If not, I believe that many of your readers will be glad to learn the objects with which Prof. Agassiz has started, with Count Pourtales and a distinguished band of skilled observers, on a scientific expedition in the United States' surveying ship *Hassler*, and to receive a brief account of what he has already done at St. Thomas and Barbados,

at which places he was obliged to touch, in consequence of defects in the vessel or her machinery.

The Professor's chief objects are stated in a letter from himself to Prof. Peirce, the Superintendent of the U.S. Coast Survey. (See NATURE, vol. V., p. 194.)

The Expedition was detained some days at St. Thomas, and the time of the Professor and his assistants was devoted chiefly to the collection and preparation of fishes, with a view to the study of the brain, and the breathing and digestive organs. Several boxes full, preserved in alcohol, were at once shipped to the United States, as the first-fruits of the Expedition.

The party arrived at Barbados on December 26, and spent four days there. The first two were devoted by the Professor to examining and studying the large collection of West Indian shells, marine and terrestrial, of corals, sponges, crustacea, and semi-fossil shells of the island, made by the Governor, Mr. Rawson. Of the marine series he wrote in the following terms to Mr. J. G. Anthony, the Curator of the Harvard Museum:—"I am having high carnival. I have found here what I did not expect to find anywhere in the world—a collection of shells in which the young are put up with as much care as the adult, and extensive series of specimens show the whole range of changes of the species, from the formation of the nucleus to the adult." He was particularly struck with the now unique specimen of *Holopus*, lately procured by Mr. Rawson, which was described by Dr. J. E. Gray in the December number of the "Annals of Natural History," and named by him, from a drawing, *H. rawsoni*, but which Agassiz, who had seen the specimen of D'Orbigny in Paris, before it disappeared, considers to be a normal specimen of *H. ranzii*, which had only four, instead of five arms. Count Pourtales recognised among the corals several similar to those which he had obtained by dredging in or near the Gulf Stream, and described in the latest No. (4) of the "Illustrated Catalogue of the Museum of Comparative Zoology at Harvard College," the presence of which on the coast of Barbados serves to indicate the close similarity of submarine life in those two distant localities.

The next two days, or rather the night of the next, and the greater part of the following day, were spent in dredging in the neighbourhood, in a depth of 60 to 120 fathoms, about a mile from the shore, whence Mr. Rawson has procured his fine specimens of *Pentacrinus Mulleri*. The *Holopus* was found on the opposite side of the island. The results were beyond the expectations, or even the hopes, of the most sanguine of the party. Only dead fragments of the *Pentacrinus* were obtained, but among the abundant spoils were four specimens of a new genus of Crinoid, without arms on the stem, (like *Rhizocrinus*?) which remained alive, with the arms in motion, until noon on the following day, under the excited observation of the party. A number of deep-sea corals, alive, crustacea, sea urchins of new species, star fish, sponges, crystalline, jurassic, and corallines, &c., and a rich harvest of shells, were obtained. Among these was a splendid live specimen of *Pleuronomaria Quoyana*, F and B, of which genus Chenü writes that only one living species, and of that only one specimen, is known. The animal exhibited remarkable affinities, and the artist accompanying the expedition was able to take several sketches of it. A large *Oniscia*, shaped like *O. cancellata* Sow. but with an orange inner lip (*O. denisoni*?), some specimens of *Phorus Indicus* Gmel., a magnificent new species of *Latiaxis*, with many exquisite specimens of *Pleuronoma*, *Fusus*, *Murex*, *Scaloria*, and three or four of *Pedicularia sicula* Sw., with innumerable Pteropods and Terebratulines, rewarded these "burglars of the deep." The Professor was delighted, and it was with reluctance he abandoned so rich a field in order to secure his passing through the Straits of Magellan at a right season.

ETHNOLOGY AND SPIRITUALISM

THE *Academy* of February 15 contains a review by Mr. A. R. Wallace, of my "Primitive Culture," where he raises a point on which I wish to make some further observations; but inasmuch as the form of publication that journal adapts it rather to criticism than to correspondence, I ask leave to change the *venue*, and make my remarks in the columns of NATURE.

In "Primitive Culture" (Vol. I., pp. 279-84), I have given an account of the widespread popular belief in "were-wolves," including under this heading the analogous belief in man-hyænas, man-tigers, &c. According to this superstition, certain human beings are considered to be temporarily transformed into wolves, hyænas, or tigers, and in these shapes to go about preying on mankind. While expressing an opinion that "the origin of this idea is by no means sufficiently explained," I have offered two suggestions as bearing on its prevalence in the world: first, that such notions are consistent with the familiar doctrines of the lower culture as to transmigration of souls and transformation of bodies; second, that certain insane persons do actually suffer under the delusion that this transformation (the idea of which popular belief has put into their minds) has really happened to themselves, and they prout about like wild beasts accordingly. Mr. Wallace disapproves of this treatment of the subject, and propounds a view of his own, as follows: "A recognition of the now well-established phenomena of mesmerism would have enabled Mr. Tylor to give a far more rational explanation of were-wolves and analogous beliefs than he offers us. Were-wolves were probably men who had exceptional power of acting upon certain sensitive individuals, and could make them, when so acted upon, believe they saw what the mesmeriser pleased; and who used this power for bad purposes. This will explain most of the alleged facts, without resorting to the short and easy method of rejecting them as the results of mere morbid imagination and gross credulity."

Let me now first observe that Mr. Wallace's explanation does not supersede my suggestions; indeed, he meets neither of the points which I endeavour, however tentatively, to deal with. He offers nothing like a reason why knavish sorcerers in districts of Europe, Asia, Africa, and America should have all hit upon the device of imposing the same peculiar delusion upon their dupes; nor does he account for the fact, vouched for by satisfactory evidence, that in certain cases the supposed were-wolf is himself utterly persuaded of the reality of his own transformation, and goes to execution believing in his offence. The proofs are, I think, convincing, here as elsewhere in the history of magic, that sorcerers were originally and still are usually more or less believers in their own magical pretensions—though very many used and use fraudulent means to enhance their supposed powers; and some, who may be reckoned among the vilest of the human race, are simply professional impostors. Yet Mr. Wallace's suggestion, though it does not do away with the need of mine, seems to me valuable as a well-directed attempt to explain a part of the matter left untouched by me. His theory that a were-wolf may be a person possessed of the peculiar faculty exerted by mesmerists, of making others delusively imagine that they see and hear what in fact does not happen, is a theory at any rate plausible, and possibly on the track of explaining much of the power belonging to sorcerers, savage and other. (I may remark incidentally that the power of mesmerists in producing anaesthesia and working on the imagination of their patients has never been contradicted by me.) Now, without committing myself to Mr. Wallace's idea, beyond saying that it is plausible and worth pursuing, I proceed to apply it somewhat rather. Granting that a were-wolf, in virtue of being a person capable of exerting mesmeric influence, can delude people, and even assemblies of people, into fancying that they perceive monstrous unrealities, the

question arises, Was any one with this were-wolf-faculty present in the room when Mrs. Guppy made her celebrated acrostatic entrance? Is Mr. D. D. Home a were-wolf? Is a professional "medium" usually or ever a person who has the power of acting on the minds of sensitive spectators, so as to make them believe they see what he pleases? Pursuing this subject yet a step farther, I have now to call Mr. Wallace's attention to an interesting fact. The sorcerers of the Abipones of South America, who by mere roaring within their tents threw the credulous savages into agonies of panic terror, caused by vivid belief that tiger-spots were in the act of coming on their (the sorcerers') bodies, that their nails were growing into claws, that they were actually transforming themselves into tigers, deadly though invisible—these sorcerers were actually the professional spiritualistic mediums of the tribe, part of whose business it was to hold intercourse with the spirits of the dead, causing them to appear visibly, or carrying on audible dialogues with them behind a curtain. Mr. Wallace, as the most eminent scientific man who has taken up what are known as modern "spiritualistic doctrines," no doubt has the ear of all who hold these doctrines. I think it may bring about investigations leading to valuable results if Mr. Wallace will inform spiritualists with the weight of his authority that he believes in the existence of a class of men who, in his words, have exceptional power of acting upon certain sensitive individuals, and can make them, when so acted upon, believe they see what the mesmeriser pleases, and who use this power for bad purposes.

With reference to other parts of Mr. Wallace's review of my work, I have to thank him for several valuable comments, while, at the same time, I venture to express an opinion that some of his objections to my ethnological treatment of spiritualism are unreasonable, and especially I wonder that so serious a student of natural science should make it a ground of complaint against me that in treating of difficult and important problems I consider it necessary to bring forward copious and widely distributed evidence. But rejoinders to reviews are seldom desirable in themselves, and my justification for the present note lies in the importance of drawing attention to a matter worth considering by persons on both sides of the spiritualistic controversy.

E. B. TYLOR

DREDGING EXPEDITIONS

THE occasion of an American Dredging Expedition recently starting, leads us to make the following remarks on such Expeditions in general, more especially upon one whose programme has lately come to our ears.

England has perhaps of all countries done the most for dredging. We have only to point to such names as Forbes, Ball, McAndrew, Wallich, Jeffreys, Wyville Thomson, and Carpenter, as among the landmarks in the cause. Indeed, for many years coast dredging has been a popular amusement with the marine naturalist and collector, and many a prize has been in this manner turned up.

In 1868 Messrs. Carpenter, Thomson, and Jeffreys were fortunate enough to obtain the use, free of expense, of a Government steamer, and, armed with a substantial grant from the Royal Society, tried their luck in the deep sea. The following year the Government again gave them the use of a vessel, and the Royal Society a further grant of 200*l.* Again in 1870 they went out at the country's expense. The great and important results obtained during these cruises are pretty well known to the scientific world, and it is unnecessary to repeat them here.

In the year last mentioned an unheard-of circumstance took place. An English yachtsman, Mr. Marshall

Hall, not only gave up the use of his yacht for the summer in the cause of Science, but bore nearly the whole expense of the cruise himself. The naturalist who accompanied them was Mr. Kent, of the British Museum, a man comparatively unknown before that time; and this was, perhaps, the reason why the Royal Society could only afford to give £50 towards the expense of apparatus, &c. As a natural consequence, the expedition was considerably crippled for want of proper gear, and they were unable to attempt deep-sea work. It is too rare for persons who are blessed with means to assist Science in any way, and when such an act of generosity does take place, it ought not to be forgotten on the part of the scientific public. Yet it is rumoured that a similar expedition to Morocco and Madeira, which Mr. Marshall Hall is arranging for the spring, is likely to be received with some coldness by some influential members of the scientific brotherhood. We sincerely hope that the rumour is incorrect.

It appears that Mr. Marshall Hall proposes to be absent from England for between three and four months; and, besides the natural history, to investigate, as far as possible, certain chemical and physical questions concerning the deep sea and its currents in the neighbourhood of the above-mentioned places. He is taking with him a young naturalist, Mr. P. T. Abraham, B.A., B.Sc., lately from Dublin, at which University he came out first in natural science honours, and where he has gained a high reputation for zoological knowledge. It is also probable that another naturalist will make up the staff. These gentlemen intend to give, besides the use of the yacht, 150*l.* or so—as much as they are able. The remaining 250*l.*—for the total cost of the expedition could not amount to much less than 400*l.*, when the items of gear, apparatus, outfit, and maintenance for such a time are taken into consideration—they hope to obtain in the form of grants from the learned societies. We feel sure that the Royal Society will be among the first to endow the work out of the fund placed at their disposal by the Government, and the best friends of Biology may wish that they had more frequent opportunities afforded them of assisting in researches in which it is fitting that in the first instance a private individual should come forward.

It is possible even that other societies may be induced to help if they have funds at their disposal. Among such societies we may mention the Zoological Society, which contains on its roll the names of men of the first rank in every department of zoology. It is true that a great portion of the funds are expended in the direction of the higher vertebrates, and that the lower animals do not receive the attention they may deserve; but still, it must be remembered that the great object of the society is the popularisation of natural history.

We hope that the *Norna's* will not be the only dredging excursion starting from British waters this year. The field that has been so ably opened up by Dr. Carpenter and his colleagues ought not to be allowed to slip away altogether from the hands of Englishmen. We know too well that other nations are not backward in following up and eclipsing the work that British pluck and genius have been the first to venture upon. The Americans are on the track, and our Continental neighbours will not be far behind.

We are glad that the extended circumnavigation expedition is in process, and we believe that if nothing unforeseen occurs, Prof. Wyville Thomson, with a staff of competent aids, will sail in the autumn on their long journey, which cannot fail to have the most important bearing on our future advance in such studies. Such a journey as this, however, instead of making more modest dredging operations of no avail, vastly increases their importance; and it is not too much to hope that the time is not far distant when men of money and leisure will more generally occupy their time in such pursuits.

SOLAR HEAT

THE calculations presented by Père Secchi, in his work "*Le Soleil*," relative to solar temperature and solar radiation, tending to discredit the result of recent investigations on the subject, I have carefully examined the "solar intensity apparatus," the indications of which form the basis of those calculations. This unique device will be found delineated on p. 267 of the work referred to, the accompanying illustration (Fig. 1) being a fac-simile of the same. It represents a longitudinal section through the centre line, thus described:—A B and C D are two concentric cylinders soldered one to the other; they form a kind of boiler, the annular space being filled with water or oil at any temperature. A thermometer, *t*, passes through a tube, across the annular space, to the axis of the cylinder; it receives the solar rays introduced through a diaphragm, *mn*, the opening, *o*, of which is very little larger than the bulb of the thermometer. A thick glass, *V*, closes the back part of the instrument, and admits of ascertaining whether the thermometer is placed in a direct line with the pencil of rays. The interior cylinder and the thermometer *t* are coated with lamp black. A second thermometer, *t'*, shows the temperature of the annular space, and consequently that of the inclosure. The whole apparatus is mounted on a support having a parallactic movement, to facilitate following the diurnal motion of the sun. The apparatus being exposed to the sun, it will be found, on observing the two thermometers, that their difference of temperature increases gradually, and that in a short time it ends by being constant.

Before pointing out the peculiarities of the contrivance thus described by Père Secchi, it will be instructive to examine his "solar intensity apparatus," manufactured by Casella, represented in Fig. 2. The manufacturer publishes the following statement regarding this instrument:—"Two thermometers are here kept immersed in a fluid at any temperature, and a third surrounded by the same conditions, but not immersed, is exposed to the rays of the sun. The increase of temperature thus obtained is found to be the same, irrespective of the temperature of the fluid which surrounds it." No one acquainted with the principles which govern the transmission of heat within circulating fluids can fail to observe that the thermometers applied above the central tube will not furnish a reliable indication of the temperature of the fluid below the same, nor of any portion of the contents of the annular space towards the bottom. Apart from this defect, it will be perceived that an upward current of atmospheric air will sweep the underside of the external cylinder, causing a reduction of temperature of the fluid confined in the lower half of the annular space. Again, the heat radiated by the bulb of the thermometer exposed to the sun will elevate the temperature of the air within the central tube, and consequently produce an internal circulation tending to heat the upper part of the fluid contained in the annular space. The effect of the irregular heating and cooling thus adverted to will be considered after an examination of the result of some observations recorded in Table A conducted at different times during the month of September 1871. In order to insure an accurate position, the instrument during these observations was mounted in a revolving observatory upon a table turning on declination axes provided with appropriate mechanism and declination circle. An actinometer being attached to the same table, the true intensity of the radiant heat, as well as the sun's zenith distance, were recorded simultaneously with the indications of the Secchi instrument furnished by Casella. Let us first consider the tabulated observations of September 2 recorded at equal intervals of three minutes. The indication of the two thermometers immersed in the fluid contained in the annular space first claims our attention, since the temperature of this fluid is

the principal element in Père Secchi's computations of solar temperature. It will be seen on referring to the second and third columns of the table that, while the upper thermometer indicates a mean temperature of $86^{\circ}9'$, the lower one shows only $79^{\circ}5'$, difference = $7^{\circ}4'$. This great discrepancy of temperature at different points of the upper portions of the annular space at which, owing to the inclined position of the concentric tubes, something like uniformity ought to exist, suggests a still greater discrepancy of temperature at the underside towards the lower termination of the tubes. In addition therefore to the observed irregularity of temperature at the upper part, shown by the table, no indication whatever is furnished of the temperature of the fluid in the annular space below the central tube, nor towards the termination at either side. Obviously, then, no accurate computation can be made of the degree of refrigeration to which the central thermometer is exposed by the radiation from the cold blackened surface of the internal tube, every part of which, as we have seen, possesses a different temperature compared with the rest, consequently transmitting radiant energy of different intensity. It will be found practically impossible, therefore, to determine the true differential temperature of the contents of the bulb exposed to the sun's rays and the fluid contained in the annular space. Hence, the differential temperature entered in the table, the result of comparing the indications of the thermometers, is manifestly incorrect. It will be found also by reference to the table that while the mean temperature imparted to the central thermometer by the sun's rays is $93^{\circ}1'$, the mean temperature of the fluid in the annular space is $83^{\circ}3'$. Consequently, the intensity of solar radiation established by the instrument is only $93^{\circ}1' - 83^{\circ}3' = 9^{\circ}79'$ Fah. Now, the sun during the recorded experiment of September 2 was exceptionally clear, the mean indication of the actinometer while the experiment lasted being $60^{\circ}05'$, thus showing that the energy developed was only $\frac{9^{\circ}79'}{60^{\circ}05'} = 0.16$ of the true radiant

intensity. The mean zenith distance, it may be mentioned, was only $33^{\circ}24'$ during the experiment. Agreeable to the table of temperatures previously published, the maximum solar intensity for the stated zenith distance is $63^{\circ}35'$; thus we find that the sun, as stated, was exceptionally clear while the trial took place, which resulted in developing the trifling intensity of $9^{\circ}79'$ Fah. The result of the experiments conducted September 6th, recorded in the table, it will be seen was nearly the same as that just related, the mean temperature indicated by the thermometer exposed to the sun being $98^{\circ}2'$, while the mean of the two thermometers immersed in the fluid was $87^{\circ}8'$, hence the differential temperature $98^{\circ}2' - 87^{\circ}8' = 10^{\circ}4'$. The mean temperature of solar radiation during the experiment, ascertained by the actinometer, was $59^{\circ}75'$, the zenith distance being $35^{\circ}33'$. Consequently, the intensity indicated September 6th was only $\frac{10^{\circ}45'}{59^{\circ}75'} = 0.17$ of the true

energy of the sun's radiant heat, against 0.16 during the previous experiment. It will be observed that the fluctuation of the differential temperature was much greater September 2nd than during the succeeding experiment, owing, no doubt, to the influence of currents of air produced by a strong breeze on the first occasion, the revolving observatory being partially open on the side presented to the sun during observations.

With reference to the small differential temperature indicated by the Secchi instrument manufactured by Casella, it may be urged that it is not intended to show the true intensity of solar radiation on the earth's surface, but simply a means of determining solar temperature. Granted that such is the object, yet the extreme irregularity of the temperature of the fluid within the annular space shows that the instrument is unreliable, a fact

established beyond contradiction by an experiment instituted September 27, 1871. On this occasion water of a uniform temperature was circulated through the annular space. This was effected by gradually charging this space from the top, and carrying off the waste at the bottom, holes having been drilled in the external casing for that purpose. The result of this conclusive experiment is recorded at the foot of Table A. It will be found on reference to the figures, that the mean difference of the two thermometers immersed in the fluid was only $64^{\circ}9' - 64^{\circ}4' = 0^{\circ}5'$, while the mean differential temperature was augmented to $79^{\circ}1' - 64^{\circ}45' = 14^{\circ}65'$ against $9^{\circ}79'$ on the 2nd of September, although the zenith distance was greater, and the solar intensity less; circumstances which ought to have diminished the indicated intensity. It is needless to enter into any further discussion of the demerits of the instrument represented in Fig. 2. We may now return to the consideration of the device delineated in Fig. 1, copied from "Le Soleil." It will be seen that the material difference of construction is that of applying only one thermometer for ascertaining the temperature of the fluid in the annular space. Possibly this single thermometer may indicate approximately the mean temperature of the upper and lower portions of the fluid above the central tube; but it furnishes no indication of the temperature below, nor at either extremity of the annular space. The inadequacy of the means adopted for ascertaining the temperature of the internal surface which radiates towards the bulb of the central thermometer having thus been pointed out, it will be well to consider whether the expedient of passing a stream of water of nearly uniform temperature through the annular space, will insure trustworthy indication. In order to determine this question, I have constructed two instruments, in strict accordance with the delineation in Fig. 1, excepting that in one of these the concentric cylinders are considerably enlarged, the annular space, however, remaining unchanged. Experiments with the two instruments prove that the enlargement does not materially influence the indications, provided water of a uniform temperature be circulated through the annular space. But these experiments have demonstrated that the size of the bulb of the thermometer exposed to the sun cannot be changed without influencing the differential temperature most materially. This will be seen by reference to Table B, which records the result of experiments with different thermometers, and tubes of different diameter, conducted October 17, 1871. As on previous occasions, the instruments, in order to insure accurate position, were attached to the declination table arranged within the revolving observatory. The bulbs of the thermometers employed were very nearly spherical, their diameters being respectively 0.30 and 0.58 ins. The upper division of Table B which records the experiment with the *small* bulb exposed to the sun, establishes, it will be seen, a differential temperature of $14^{\circ}4'$ for the instrument having the 1½-in. central tube, and 16° for the one having the 3-in. central tube. Referring to the lower division of the same table, it will be seen that when the thermometer with the *large* bulb is exposed to the sun, the differential temperature reaches $22^{\circ}5'$ in the instrument containing the 1½-in. central tube, and $21^{\circ}1'$ in the one having the 3-in. tube. We thus find that, by doubling the diameter of the bulb of the thermometer exposed to the sun, all other things remaining unchanged, an augmentation of the differential temperature amounting to nearly one-third takes place. This fact proves the existence of inherent defects fatal to the device delineated in Fig. 1, rendering the same wholly unreliable.

Agreeably to the doctrine of exchanges, the diameter of the bulb is an element of no moment, since the internal radiation towards the same—*provided its temperature be uniform*—depends solely on the temperature and angular distances of the radiating points of the enclosure. Infallibility of the "solar intensity apparatus" has evidently

been taken for granted on the strength of the soundness of this doctrine, as we find no allusion to the size of the bulb in M. Soret's account of his observations of solar intensity on Mont Blanc; nor does Mr. Waterston, who employed a similar instrument during his observations in India, advert to the dimensions of the bulb of the ther-

FIG. 1.

mometer exposed to the sun. These physicists apparently overlook the fact that, while the entire convex area of the bulb is exposed to what may be considered the cold radiation from the enclosure, only one half receives radiant heat from the sun. This circumstance would be unimportant if the heat thus received were instantly trans-

FIG. 2.

mitted to every part; but the bulb and its contents are slow conductors, while the conducting power diminishes nearly in the inverse ratio of the square of the depth. Consequently, by increasing the diameter, the parts of the bulb opposite to the sun will receive considerably less heat in a given time than if the diameter be diminished.

TABLE A, showing the result of observations made with Secchi's "Solar Intensity Apparatus," manufactured by Casella.

J. ERICSSON

MAGNETICAL AND METEOROLOGICAL OBSERVATIONS AT HAVANA

ON the 9th and 10th day of November I noticed on my instruments two strong magnetic perturbations, during which a series of extraordinary observations was taken at intervals of five, of ten, and fifteen minutes. From these I was naturally drawn to think that an aurora borealis would be seen in higher latitudes, and was waiting for a confirmation of my views.

This I found in the numbers 16th and 23rd of November of your scientific journal, NATURE, which I have just received, and in which I see with great pleasure the

Curves of the Horizontal Magnetic Force on the 9th and 10th days of November, 1871, compared with the Mean Force of the whole month.

SCALE $\left\{ \begin{array}{l} 1 \text{ hour} = 0^{\text{m}} .01 \text{ in the line of the abscissa} \\ 5 \text{ divisions of the scale of the Bifilar Magnetometer} = 0^{\text{m}} .01 \text{ in the line of the ordinates.} \end{array} \right.$
Each one of these divisions of the scale corresponds in parts of horizontal force to $K = 0.000099573$.

description of the aurora borealis seen in England on the 9th and 10th of November in perfect accordance with my observations of those days.

As it will not be devoid of interest to know to what an extent an aurora borealis, when seen in England, exerts its influence on the magnetic variations of a place situated in the Tropics and in very remote longitude, I take the liberty of sending you the curves of the horizontal magnetic force as registered by the bifilar magnetometer on the 9th and 10th of November, together with the curve of the mean horizontal force of the whole month. A comparison between them and those taken in other places will be, I hope, very pleasant to those who are interested in magnetic researches.

My observations on the bifilar magnetometer are referred to the temperature of 77° Fah. The variation of

the thermometer attached to it was $0^{\circ}8$ during the whole perturbation.

The magnetic instruments I make use of are those of the Observatory of Makerston, Scotland, which were arranged and sent many years ago to this Observatory by order of General Sabine at the request of P. Secchi, of the Roman Observatory.

Another perturbation, although not so intense as those already described, was observed on the 2nd of November. It began at ten o'clock in the morning, and lasted the whole day.

A very remarkable one was also observed on the 17th and 18th of June; it began at ten o'clock in the evening of the 17th.

On the 21st of August, while a hurricane was felt in St. Thomas, and an aurora borealis seen from the Observatory of Dun Echt, Aberdeen, I noticed an extraordinary variation, which attained its maximum between four and six o'clock in the afternoon. A similar one occurred on the 24th.

Finally, on the 16th and 17th of August two great hurricanes swept the shores of Florida, and their influence upon the magnetic force can be perfectly noticed on the curves of those days.

BENEDICT VINES

Havana, Dec. 21, 1871

NOTES

WE alluded some time since to the threatened destruction of one of the most notable megalithic monuments in this country, the Great Circle at Avebury, in Wiltshire. All archaeologists will be glad to hear that Sir John Lubbock has added one more to his eminent services to science by the purchase of the site on which the Circle stands. It is right also that the meed of praise should be awarded to those of the residents in the district whose zeal has been directed towards the attainment of this object, and who have thus shown their sense of the value of the monument which is one of the glories of their county. We refer especially to the Rev. Bryan King, the vicar of the parish, Mr. Kemm, Mr. George Brown, and the Rev. Alfred Charles Smith, Hon. Secretary of the Wiltshire Archaeological and Natural History Society. It is to be hoped that their example will stimulate similar zeal for the preservation of monuments in other parts of the country.

DR. T. STERRY HUNT, chemist to the Canadian Geological Survey, has been appointed to the chair of Geology in the Massachusetts Institute of Technology.

MR. HENSMAN has been appointed Lecturer on Botany at the Middlesex Hospital, in the place of Dr. T. S. Cobbold, F.R.S., who has received the appointment of Lecturer on Parasitic Diseases.

AT the meeting of the Royal Geographical Society on Monday evening last, Sir Henry Rawlinson, the President, announced that the vessel with the Livingstone Expedition on board arrived at Malta on the 23rd inst., and was to reach Port Said on Sunday, and leave Suez on Monday night. By the accounts to hand all on board were pronounced to be well, and in the highest spirits. The finances of the expedition were in a highly satisfactory state, many contributions being remarkably striking, as showing the great interest taken in the enterprise not only in this, but in many distant countries. A contribution of 100 guineas had been received from a former member at Stockholm, who had always taken a deep interest in the travels and discoveries of Dr. Livingstone. The Italian Royal Geographical Society had also sent a contribution of 15*l*. 15*s*., while national committees to assist the fund had been formed in Scotland and Ireland, who were working most energetically. The town of Glasgow has subscribed 1,000*l*., Edinburgh 400*l*., and Dublin promised to be equally

generous. Similar interest had been awakened in Chicago, whence too, had come in to be placed at the disposal of the Livingstone Expedition; and on the whole it might be said the announcement of the undertaking had been hailed with general satisfaction throughout the civilised world. Exclusive of two sums of 400*l.* and 600*l.* odd, the latter the balance of the former Government grant, there was now standing to the credit of the expedition a sum of 4,200*l.*

THE following gentlemen were on Saturday last elected to Junior Studentships in Natural Science at Christchurch, Oxford:—M^r. D. A. Greswell, Commoner of Balliol College, M^r. B. Hainsworth, of Manchester Grammar School, M^r. W. A. Smith, of Clifton College. These scholarships are of the annual value of 75*l.*, together with the rooms rent free.

AT the examination recently concluded at the Melbourne University, there were no less than 225 competitors, of whom 86 passed the matriculation examination, and 108 the civil service examination. Many of the names in the former were included in the latter, but on the other hand, there were some who passed the larger, the matriculation examination, who did not pass the smaller examination, that for the civil service. The reason is, that for the matriculation any six subjects serve to qualify, while for the civil service, of the four subjects, two given ones are essential. The examinations this time had a novel feature, from there being three lady candidates, all of whom passed. The Council of the University, however, has passed a resolution to the effect that the successful ladies should not be allowed to matriculate. No reasons have been given for this decision, but it is presumed that the obstacle is a legal one.

THE *Academy* states that the President of the Geographical Society of Italy has written to the papers to say that the Conservator of the Bibliothèque Royale of Belgium has discovered a MS., in twelve chapters, containing the original autograph account of the discovery of Australia by Manuel Godinho, a Portuguese navigator, who touched there in 1601, and whose priority to the Dutch sailors, who arrived three or four years later, has been unduly neglected. M^r. Ruelens vouches for the authenticity of the MS., which was brought to light at the Antwerp Exhibition, though it passed unnoticed in the crowd.

PROF. CLEVELAND ABBE, in an article entitled "Historical Note on the Method of Least Squares," in the *American Journal of Science and Arts*, shows that this method, though first published in a printed form by Le Gendre in 1806, and invented by Gauss in 1795, was published in 1808 by Prof. Robert Adrain, at that time in New Brunswick, N. J., in the "*Analyst*," he having been independently led to this invention by the study of a prize problem offered some months previously in that periodical.

AN important addition has been made to the list of works devoted to inquiries and instructions in regard to the great fisheries in the form of a paper, by M. Achille Costa, upon the fisheries of the Gulf of Naples, published by the Royal Institute for the Encouragement of Natural Science, &c., of Naples. The subject is treated under four heads: first, a description of the various modes by which fishing is prosecuted in the Gulf of Naples, whether commendable or otherwise, with engravings of the nets and other apparatus used; second, the consideration of the various modes of fishing, and their relationship to the present and prospective supply; third, memoranda in regard to the localities in which the different kinds of fish and other marine animals are to be found, and the favourite places for depositing their spawn; and fourth, a systematic catalogue of the different species of marine animals found in the Gulf of Naples, and gathered for the purpose of serving as food.

PROF. MARSH reports to the *American Journal of Science* the

discovery, during his explorations in 1871, of a remarkable fossil bird. It was found in the Upper Cretaceous of Western Kansas, and the remains consist of the greater portion of the skeleton, at least five feet in height, and which, although a true bird, as is shown by the vertebrae and other parts of the skeleton, differs widely from any known recent or extinct forms of that class, and affords a fine example of a comprehensive type. The bones are all well preserved. The femur is very short, but the other portions of the legs are quite elongated. The metatarsal bones appear to have been separated. On his return the professor proposes to describe this unique fossil under the name of *Hesperornis regalis*.

IN the expedition against the Loshais, who have attacked our tea plantations in Cachar, the interests of science have been cared for. Lieutenant Browne, 44th Foot, known in India as an able naturalist, has charge, with a trained native from the Indian Museum at Calcutta, to act as collector. Something is expected from the unexplored regions of the Loshai country.

HERR PAUSCH, a member of the late German polar expedition, recently made a communication to the German Anthropological Society in regard to certain abandoned habitations of the Esquimaux in East Greenland. He remarked that at each of seven different points they found three stone houses, some of them certainly over one hundred years old. These were winter huts, the remnants of their summer abodes being indicated by stone rings. In many places there were indications of stone graves, and from the skeletons found in them tolerably well-preserved crania were obtained, agreeing with the Eastern Esquimaux type as described by Virchow, and exhibiting the carnivorous habit in the highest degree. Remains of wood carving, tolerably well executed, occurred with the dead bodies, and in the heap were found bone knife-handles, harpoons of bone, arrow-tips, and even knife-shaped pieces of iron, probably obtained from the English expedition of 1823.

IN referring to the explorations of Dr. Hayden about the Yellow Stone Lake during the past summer, mention was made of the fact that the trout all seemed very much infested with a peculiar kind of worm, which interfered considerably with the enjoyment of eating them. Specimens of this animal have been submitted to Prof. Leidy, of Philadelphia, who reports that they represent a new species or type of worm, of the genus *Dibothrium*. Two species of the genus have long been known as infesting salmon and other members of the trout family in Europe, but both are decidedly different from the new form just mentioned.

THE Trustees of the Museum of Comparative Zoology at Harvard College, Cambridge, U.S.A., have issued their Annual Register for 1870, together with the Report of the Director, Prof. Agassiz. It is stated that the accessions to the Museum during the past year had been very great and of surpassing importance. Foremost stands Deyrolle's collection of Curculionidae, presented by Mrs. A. Hemenway; next the collection of Galls of Baron d'Osten-Sacken, presented by him; then the magnificent collection of Fossil Plants of M. Lesquereux, especially remarkable for the exquisite selection of the specimens it contains, and that of Insects of Texas, made by M^r. J. Boll, both of which have been bought by the Museum; and not least the unparalleled collection of Neuroptera, brought to America by Dr. Hagen, and now deposited in the Museum. There are special reports on the Mammalia and Birds by M^r. J. A. Allen; on the Fishes by Dr. Franz Steindachner; on Conchology by J. G. Anthony; on the Articulata by Dr. Hagen; and on the Palaeontological collections by Prof. Shaler, M^r. J. B. Perry, and Dr. G. A. Macack.

WE have received the Register of the Trustees, Officers, and Students of the Lehigh University, South Bethlehem, Penn.,

U.S., for the year 1871-72. The University was founded by a gift, in the year 1865, from the Hon. Asa Parker, of the sum of 500,000 dols., and a site of land containing 56 acres in the Lehigh Valley. The purpose of the founder was "to provide the means for imparting to young men of the valley, of the state, and of the country, a complete professional education, which should not only supply their general wants, but also fit them to take an immediate and active part in the practical and professional duties of the time. The system determined upon proposes to discard only what has been proved to be useless in the former systems, and to introduce those important branches which have been heretofore more or less neglected in what purports to be a liberal education, and especially those industrial pursuits which tend to develop the resources of the country,—pursuits, the paramount claims and inter-relations of which natural science is daily displaying—such as Engineering, Civil, Mechanical, and Mining; Chemistry, Metallurgy, Architecture, and Construction." For this purpose, special classes in all the above-named subjects have been instituted; and by the liberality of Robert H. Sayre, one of the trustees of the University, an Astronomical Observatory has been erected in the University grounds and placed under the care of the Professor of Mathematics and Astronomy, for instruction of students in Practical Astronomy. The Observatory contains an equatorial, by Alvan Clark, of six inches clear aperture, and of eight feet focus; a zenith sector, by Blunt; a superior astronomical clock, by William Bond and Sons; a meridian circle and a prismatic sextant, by Pistor and Martins.

DR. E. ASKENASY, in his "Beiträge zur Kritik der Darwinischen Lehre," contrasts the doctrine of Natural Selection as carried out to its full extent by Darwin in his "Origin of Species" and "Variation of Animals and Plants under Domestication," with the modified form of theory adopted by Nägeli in his "Conception and Origin of Species in Natural History."

The first part of Dr. N. J. C. Müller's "Botanische Untersuchungen" treats of the separation of carbonic acid by the green parts of plants under the influence of sunlight, and is illustrated by a plate, delineating, in the form of curves, the effects of the different rays in the solar spectrum.

DR. GERARD KREFFT, in a paper on the Australian Vertebrata, Fossil and Recent, points out how valuable would be a general study of Natural History in a country like Australia, where every pool and creek teems with animal life, numerous mussels, various kinds of cray-fish, turtles, frogs, lizards, freshwater snakes, and other creatures, all of which are more nourishing to a starving human being than the wretched nardoo on which the lamented Burke and Wills tried to subsist. He advocates the establishment of district museums, and that the children should be taught to observe the habits and economy of different animals, in particular of those which are useful, by which means the wealth of the country would be much increased. Dr. Krefft promises hereafter a complete natural history of Australian Vertebrates, which will be the first ever published.

THE "American Horological Journal," published in New York, of which several numbers lie on our table, contains not only articles of special interest to manufacturers and vendors of clocks and watches, but others on Spectrum Analysis, and kindred scientific subjects.

"INDEX TO PRICES" is responsible for the following:—The demand for human hair is so great that it is impossible to supply it. Price has risen to 16s. a pound. As much as 1,000 dols. has been offered for a "head of hair" six feet long. Some ladies dress fifty to sixty miles of hair every morning.

AT the meeting of the Society of Arts held last week, Dr. Brands, Inspector-General of Forests to the Government of India, said that the cinchona plantations were now become almost

forests. Before long they would be able to be coppiced every six or eight years, just as oak coppices were treated in Germany, Scotland, and elsewhere, every fifteenth or eighteenth year, and this would probably be the simplest and most profitable mode of getting the bark. The introduction of ipecacuanha into India was also alluded to. Dr. Masters expressed an opinion that there must be dozens, if not scores, of plants indigenous to that country, having the same medical properties as ipecacuanha, which could be much more easily utilised.

ACCORDING to the editor of the *Journal of Conchology*, of Paris, the Paris Museum received twenty-three shots from cannon of the German besiegers in the course of the siege, destroying many of the plant-houses. Two of these balls exploded in the conchological laboratory, in the care of Prof. Deshayes, causing great injury to the specimens, and the *Septaria* in the general collection were literally ground to powder. The large collection of shells of the lower sands of the Paris basin was entirely destroyed. This is much to be lamented in a scientific point of view, as it contained many types. A ball also passed through a glass case containing the *Unios* and *Anodonta*.

AT a late meeting of the State Dental Society of Pennsylvania one of the members, Dr. Barker, is reported in the *Dental Times* (July 1871) to have read an essay on Irregularity of Teeth, the circumstances favouring it, and suggestions on its prevention and treatment. The essayist held the opinion that a retrograde metamorphosis is going on in human teeth. To obviate this there must be improvement in the mode of living, the use of more substantial food, and from the time of the appearance of the deciduous teeth children should be under the care of an educated dentist; so that when the permanent teeth begin to erupt they may be properly guided, and a regular arch result. As a rule the first permanent molars should be extracted to make room for the succeeding teeth, for the jaws of the Anglo-Saxon race are shortening, and no longer have room for thirty-two teeth. How will this end?

ON January 28, the town of Schamachi, in the Caucasus, was totally destroyed by a succession of earthquakes. Few houses remain standing, and many lives have been lost.

A CORRESPONDENT of the *Globe* writes to say that the recent intelligence, describing the total destruction of the city of Oran in Child by an earthquake, must be a mistake. He says, that the city of Oran in the province of Salta, in the Argentine Confederation, was destroyed by an earthquake, on October 22, last year, but very few lives were lost. This is the earthquake referred to in NATURE (p. 251), but the date was there wrongly given as November 15.

BETWEEN ten and eleven at night, on December 12, two shocks of earthquake were felt at Serampore, in quick succession. The second and the strongest lasted about ten seconds, and seemed to move from north to south. The vibrations were very strong, but no great amount of damage was done.

THE Rangoon Mail states that on the night of December 12, an earthquake which lasted about ten seconds was felt at R'more. The wave appeared to travel from north-east to south-west. The shocks were stated to be severe, and followed in quick succession, but no damage is reported in the town. The earthquake occurred on the night of the new moon. A letter received from Herzsadk states that an earthquake was felt there on the same night. In another paragraph we give an account of an earthquake felt at the same time at Serampore.

ON the 12th of December at 10.5 P.M. an earthquake was felt at Calcutta with a shock lasting eight seconds, and moving from east to west. It was felt at Dacca about the same time, but its direction was considered to be from north to south. It was also felt at Akyab and in Burmah.

WALLACE ON THE ORIGIN OF INSECTS*

AMID all the discussions to which the question of the Origin of Insects has given rise, it is to me surprising that one of the most ingenious and remarkable theories ever put forth on a question of natural history has not been so much as once alluded to. More than six years ago, Mr. Herbert Spencer published, in his "Principles of Biology," a view of the nature and origin of the annulose type of animals, which goes to the very root of the whole question; and, if this view is a sound one, it must so materially affect the interpretation of all embryological and anatomical facts bearing on this great subject, that those who work in ignorance of it can hardly hope to arrive at true results. I propose, therefore, to lay before you a brief sketch of Mr. Spencer's theory, with the hope of calling attention to it, and inducing some of you to take up what seems to me to be a most promising line of research; and, although the question is one on which I feel quite incompetent to form a sound judgment, I shall call your attention to the light which it seems to throw on some of the most curious anomalies of insect structure.

The theory itself may be enunciated in very few words. It is, that insects, as well as all the Annulosa, are not primarily single individuals, but that each one is a compound, representing as many individuals as there are true segments in the body, these individuals having become severally differentiated and specialised to perform certain definite functions for the good of the whole compound animal.

Mr. Spencer first calls attention to the fact, that among the undoubtedly compound animals (which are almost all found in the sub-kingdoms, Cœlenterata and Molluscoïda) the several individuals are rarely combined in such a manner as to necessitate any physiological division of labour among them. The associated individuals of a Hydrozoan or an Ascidian are each free to spread their tentacles, to draw in currents of water, and to select their food, without in any way interfering with each other, because the compound animal is either branched or approximately hemispherical, and thus there is no necessity for any of the combined individuals to become especially modified with regard to the rest. But should a compound animal have its component individuals arranged in a linear series, there would most probably arise a marked difference of conditions between the two situated at the extremities and those between them. If they remained united, some modification must have occurred to adapt each to its condition. But if, further, the series should be fixed at one end, the other being free, a new differentiation must arise; for the two ends being very differently situated, the intermediate ones will also differ accordingly as they are nearer one end or the other. Here there is a cause for the differentiation of united individuals that does not exist in any branched or other symmetrical arrangement than a linear one. Some of the Salpidæ show such a rudimentary linear aggregation, but their mouths and vents being lateral the individuals are so similarly situated that no differentiation need occur. A little consideration will show us that this is one of those cases in which perfectly transitional forms are not to be expected. A permanent union of individuals in a linear series, such as to necessitate differentiation of function among them, could only be effected by a series of co-ordinated gradations, each of which would have so great an advantage over its predecessor as to necessitate its extinction in the struggle for existence. We cannot expect to find the union without the differentiation, or the differentiation without the complete union; and it will, therefore, be impossible to prove that such was the origin of any group of animals, except by showing that numerous traces of separate individualities occur in their organisation, and cannot be explained by any of the known laws of development or growth in animals not so compounded.

In the structure of the lower Annelids we do find strong indications of such an ancestral fusion of distinct individuals. These animals are composed of segments, not merely superficial, but exhibiting throughout a wonderful identity of form and structure. Each segment has its branchiae, its enlargement of the alimentary canal, its contractile dilatation of the great blood-vessel, its ganglia, its branches from the nervous and vascular trunks, its organs of reproduction, its locomotive appendages, and, sometimes, even its pair of eyes. Thus every segment is a physiological whole, having all the organs essential to life and multiplication. Again, just as other compound animals increase by gemmation or fission, so do these. The embryo leaves the

egg a globular ciliated gemmule; elongation and segmentation then take place, always in the hinder part, so as to elongate the compound animal without interfering with the more specialised anterior segment. In the Nemertidæ, and some Planaria, spontaneous fission occurs, each part becoming a perfect animal, and in the Tænia this is the usual mode of reproduction. The account given by Professor Owen in his "Comparative Anatomy of Invertebrates" is very suggestive of Mr. Spencer's view. He says:—"On the first appearance of the embryonic annelid it usually consists of a single segment, which is chiefly occupied by a large mass of unmetamorphosed germ-cells. And these are not used up, as in higher animals, in developing the tissues and organs of an undivided or individual whole, but, after a comparatively slight growth and change of the primary segment, proceed in the typical orders to form a second segment of somewhat simpler structure, and then repeat such formations in a linear series, perhaps more than a hundred times. So that we may have a seeming individual annelid, consisting of many hundred segments, in which a single segment would give all the characteristic organisation of such individual, except some slight additions or modifications, characterising the first and last of the series." He also tells us that spontaneous fission has now been observed to take place in almost every order of Annullata; and, in many cases, artificial fission produces two distinct individuals. In some cases the compound animal consists of very few segments, three only in the genus *Chaetogaster*, the fourth always separating as a zooid, and forming a new animal. In the higher Articulata, the process of gemmation goes on to a considerable extent in the egg, and even afterwards in some cases, but more or less irregularly. Thus the larva of *Iulus* is hatched with eight segments, and at the first moult it acquires six new ones, which are added between the last and the penultimate.

The gradual fusion of the once distinct individuals into a complete unity, is shown in a very interesting manner as we advance from the lower to the higher forms. In the Annelida, Dr. Carpenter tells us, the spiracles of each segment are separate, and do not communicate internally with those of other segments. In the Myriapoda they partially communicate, while in the Insecta they communicate perfectly by a system of anastomosing vessels. The same thing is indicated by the various positions of the chief spiracles. In *Smythurus* among the Poduridæ there are only two, opening under the side of the head immediately beneath the antennæ. In Solpugidæ (Arachnidæ) they are situated between the anterior feet; in some spiders they open near the end of the abdomen, in others at its base. The position of the mouth and eyes at the anterior extremity of the body, and the vent at the posterior, are obviously what would arise as soon as any specialisation of function in the series of zooids occurred. It is not, therefore, surprising that we never find these change their position. But for the respiratory and generative organs there is no such necessity for fixity of position, and as they existed originally in every segment, we can well conceive how, as articulate forms become more and more modified, it would sometimes be useful to the compound animal for these organs to become abortive or developed in different parts of the body. We have seen that this is to some extent the case with the former organs, but it occurs to a much greater extent with the latter.

The most generalised form is to be seen in the intestinal worms, each segment of which possesses a complete hermaphrodite reproductive apparatus; so that, in this respect, no less than in their capacity for spontaneous fission, these creatures are really what we should expect the early type of compound animals to be. This, however, is a rare case, but even in the much higher leeches there are testes in no less than nine of the segments, and Dr. Williams discovered a direct passage from the spermatheca to the ovaries, which seems to indicate internal self-fertilisation. It is, however, in the lower Arthropoda that we find the most curious diversities in the position of these organs. In the Glomeridæ the genital openings in both sexes are situated in the third segment, just behind the insertion of the second pair of limbs. In the Polydesmidæ the female organs are in the third segment, while those of the male are in the seventh segment. In *Iulus* the same organs are situated in the fourth and seventh segments respectively. The Chilopoda, on the other hand, have them near the end of the body, as in most insects. In the Acarina the ovaries open on the middle of the abdomen or on the under side of the thorax, either between or behind the last pair of legs. In spiders the seminal orifice is at the base of the abdomen, but the palpi are the intromittent

* Extracted from an Address read at the Anniversary Meeting of the Entomological Society of London on the 22nd January, 1872, by Alfred R. Wallace, F.L.S., F.Z.S., President, &c.

organs; these are spoon-shaped, and are besides armed with horny processes, hooks, and other appendages, and must be looked upon as true generative organs. In the Astacidae the sexual organs of the male are at the base of the first pair of abdominal legs, those of the female at the base of the third pair. Among the true winged-insects there is one remarkable case of abnormal position of these organs, in the dragon flies, which have the seminal vessels in the ninth, while the complex male sexual organs are situated in the second, abdominal segment. It is interesting to note that this curious anomaly occurs in an order which is considered to be of the greatest antiquity and most generalised type among the true insects.

There are many other facts of a similar character to those I have now touched upon, and they all become clearly intelligible on the theory of Mr. Spencer, that the Annulosa are really compound animals, or, as he expresses it, "aggregates of the third order;" while the other great groups of highly organised animals—Mollusca and Vertebrata—are typically simple animals, or "aggregates of the second order," (the cells of which their structures are built up being "aggregates of the first order"). Nothing of a similar character is to be found among the two latter groups. No molluscous or vertebrate animal can be divided transversely so that the separate segments shall be in any degree alike, and contain repetitions of any important organs. The distinct separation of parts in the vertebral column has been acquired, for it is less visible in the lower types than in the higher (the reverse of what obtains among insects), and in the lowest of all is quite absent; while in none is there any corresponding multiplicity or displacement of respiratory, circulatory, or generative organs. The vertebral column corresponds rather to the segmented shell of the Chiton, and has no more relation than it to the essential plan of the more important vital organs. Neither does any mollusk or vertebrate undergo spontaneous fission, nor that complete and progressive segmentation in the process of development which is characteristic of all Annulosa; nor do they ever exhibit the phenomena of parthenogenesis or alternation of generations, the essential feature of both which is, that numerous individuals are produced from a single fertilised ovum, by a process analogous to (or perhaps identical with) ordinary gemmation, and both which phenomena sometimes occur even among the higher insects.

In concluding this short sketch of a remarkable theory, I would observe, that if it is a true one it at once invests the objects of our study with a new and exceptional interest; because they are the most highly developed portion of a group of animals which will, in that case, differ fundamentally in their plan of structure from all other highly organised forms of life. In the study of the habits, instincts, and whole economy of insects, we shall have to keep ever in view the conception of a number of individualities fused into one, yet perhaps retaining some separate-ness of mental action, a conception which may throw light on many an obscure problem, and which will perhaps materially influence our ideas as to the nature of life itself. We must remember also, that if the insect is really a compound animal, then the only true homology that can exist between it and a vertebrate, or a mollusk, will be one between a single segment and an entire animal, and the search after any other will be so much lost time. Especially must the acceptance of this theory have an important bearing on all embryological and genetical studies; and if the facts and arguments adduced by its learned and philosophical author do make out even a *prima facie* case in its favour, it must deserve the careful and unbiassed consideration of all who endeavour to solve the problem of the Origin of Insects.

THE AUSTRALIAN ECLIPSE EXPEDITION

WE have already announced that no scientific results are to be expected from the Australian Eclipse Expedition, owing to the unpropitious state of the weather. The following particulars are obtained from the *Melbourne Argus*:—

"The five days intervening between the arrival at No. VI. Island and the eclipse were employed by the astronomical party in erecting and testing the instruments. Tents had to be put up, brick foundations and pedestals built, and distances determined. There was plenty of hard work, and the time at the disposal of the astronomers was found to be none too much. Nor were those who had to sleep on shore with the instruments to be envied. Possession of the island was hotly disputed by

legions of rats, who behaved in the most impudent manner. They boldly eyed the operations in the daytime, winking wickedly from behind the tufts of grass. Every night they held a corroboree in the tents, coursing over the instruments and the forms of the wearied sleepers, gnawing hats and any baggage which promised a toothsome morsel; and in some instances they had the audacity to bite the men who attempted to brush them away. The passengers filled up the interval by visits to the mainland, and one or two of the neighbouring reefs and islets. On Thursday, December 8, Mr. Moore formed a party and went to Cape Sidmouth, the boat carrying provisions for three or four days. A native on the beach seemed much alarmed at their approach. When they landed he ran off at full speed and was not seen again. Only two other blackfellows showed themselves, though the tracks and campfires proved that there were many in the neighbourhood. These blacks were known to be hostile, and it was necessary to take precautions to guard against a surprise. The master of the schooner *Challenge*, from Sydney, bound for Cape York, passed with his vessel a few yards astern of the *Governor Blackall* that morning. On hearing that a party had set out with the intention of landing at Cape Sidmouth, he expressed the consoling opinion that if they entered the bush they would never come out of it again. But no such disaster befel.

"On the hills, which rose abruptly a few hundred yards from the beach, were well-defined quartz reefs, and the neighbourhood presented all the appearance of auriferous country. A few miles from Cape Sidmouth was found an enormous heap of the bones of the dugong, the strange mammal which inhabits these seas. There were nearly two tons of bones, piled up in fantastic array, with all the skulls on top. At every turn were ant-hills, rising in solid cones from 6 ft. to 12 ft. high, and almost as hard as granite. Some of them had fine pinnacles, and these airy minarets, clustered together in graceful shapes, had a very pleasing effect. The numerous screw pines were also an agreeable feature in the landscape. The mountains, eight or ten miles inland, were well wooded, with occasional abrupt squares of grassed land.

"Mr. Moore prosecuted his botanical researches on the mainland during two days. Those who understand botany may be interested to learn from his account that the high ground at the cape is sparsely covered with stunted growths and trees, chiefly *Eucalypti* and *Grevillea chrysanthra*. Advancing into the interior, broad-leaved acacias and arborescent species of *Hakea* and *Allocasua* principally characterise the open forest country. There are belts of thick jungle scrub of no great width, in which a very slender and graceful palm, which is believed to be new, occurs in great abundance. A species of *Nepenthes*, or pitcher plant, is also found in great profusion. Aralaceous trees are numerous. Ferns are scarce, but in the open forest the ground is thickly covered with *Schizaea dichotoma*. A very remarkable plant was found as an undergrowth in this, having large white bracts and bright green foliage. It is supposed to be a species of *Mussenda*. Toward the north of the cape is a long, low, flat country, chiefly covered with mangrove. The sandy patches contain a variety of undershrubs and climbers, with a tree here and there. The silk-cotton plant (*Cochlospermum gossypium*) also varies the scene with its delicate flower. Among these shrubs a very interesting plant—a species of *Eugenia*—was found. It bears a fruit about the size and colour of a cherry, having a pleasant sub-acid flavour. This fruit was largely eaten by the party, and the tree which bears it is supposed to be well worthy of cultivation. The vegetation is otherwise principally characterised by a species of *Busbeckia*, *Elæodendron*, *Hibiscus*, *Bauhinia*, and a species of *Banksia*. After leaving the mainland the party visited No. VII. Island of the Claremont group, where Mr. Brazier added an *Auricula* and a *Bulmus* to his previous collection of shells, which included specimens of the genera *Diplommatina*, *Pupa*, *Halcicornis*, *Helix*, *Truncatella*, *Pythia*, and *Cassidula*. Had the expedition selected a portion of the mainland for the observing-point, there would have been some interesting and extensive explorations in the interior. The party were fully equipped with arms and ammunition, some supplied by the Government and some privately owned, but with the ship nine miles off, and the limited time at our disposal, much exploration was impracticable. In any case, there was no anchorage for the vessel within two miles of the shore, and that was one of the reasons why the island was preferred for the observatory.

"On Thursday afternoon, some of the excursionists went in the captain's boat to look for shells on a small sandbank which had come into view, and landed on an island considerably smaller

than the fish that Sindbad mistook for *terra firma*. It was intended to visit No. VII. Island, but it seemed that the country we were in search of had gone under water—their custom in the afternoon—and we sailed over part of it. On Friday a visit was paid to the reef, which extends for three or four miles from one extremity of No. VI. Island. The party landed on a patch of sand, and waded about three miles in 2 ft. of water over a coral bottom, in quest of shells. Here we had the wonders of the deep and its strange inhabitants laid at our feet in all their rich variety of colour. Some curious specimens were obtained. There were enormous clams, capable of holding a man's foot in their grip, abundance of *bêche-de-mer*, pearl oysters, all kinds of star fish (some of the most beautiful *ulmarine*), and many sorts of coral. One member of the party picked up a handsome live conch shell, weighing about 14 lb. Another was delighted with a strange creature belonging to the star fish order. When first taken from the water it had all the appearance of a pentagonal plum cake of about 2 lb. weight, beautifully encrusted with sugar crystals and profusely ornamented with coloured caraways. But removed from the sea water the glories of this appetising-looking creature only survived a brief period. When we had been a couple of hours prospecting on this rocky bottom of the ocean the tide rose rapidly, and we had no sooner got into the boat than the whole reef dropped out of view. The attractions of No. VI. Island proper were exhausted for the majority of people in a very brief space, but one or two were sometimes to be seen meandering along the beach, the very pictures of placid contentment. The presence of a porter bottle in one hand and an oyster knife in the other seemed to suggest that they had been visiting some of the oyster beds. They were so full of blessed content on that conversation was superfluous, and on these occasions we passed them without making a remark to disturb their dreamy happiness.

"Repeated attempts had been made since leaving Sydney to catch fish, but without success, only one small one having been hooked. This afternoon, however, great sport was afforded by the sharks. The bathers who went over the ship's side every morning had been warned that there were several of these villainous footpads of the sea about; but nothing but the sight of these rapacious monsters on deck sufficed to induce them to abandon the practice. The method adopted in catching these sharks enabled both anglers and rifle-men to take a part. As soon as a shark was hooked his head was drawn about six inches out of water, and three or four conical balls lodged in that ugly flat prominence settled him before he was hauled on deck to be drawn and quartered. In this way six, measuring from 9 ft. to 12 ft. in length, were disposed of in the course of an hour and a half, besides two which were shot in the sea, and turned over on their backs to sink. After this experience the morning ablutions of the company were limited to splashing about the decks under the hose.

"Most of the company slept through the night on deck. With the marvels of the stellar firmament above, whichever way the eye was directed, we became contemplative astronomers, like the Chaldean shepherds of old. The striking grandeur of the sky formed an endless scene to gaze at and admire. Little wonder that the ancients made the heavenly bodies objects of religious veneration. When the sun had finished his daily round, we watched the lesser light that rules the night, making her stately procession through the heavens, and the infinite variety of stars moving in concert through boundless space. There is much of the charm of romance in the study of the science which teaches us that there are other globes, in comparison with which the earth is but a speck, and proves to us that the 'patines of bright gold' with which the sky is inlaid are not simply points of light, but worlds like our own, with systems of satellites moving in their appointed courses in obedience to the laws of nature. These unknown countries afford abundant scope for interesting speculation. The mind endeavours to picture the circumstances of their inhabitants, and to conjecture, by some earthly standard, what their pursuits may be. But the imagination refuses to believe that the occupants of these bright worlds are subject to the conditions which bind those who dwell upon 'the dim spot which men call earth,' and that they have cities like ours, with their sins and their sorrows. There were some stars in the firmament which old residents of Australa had not seen for many years. While our vessel was progressing northwards, constellations unknown in the south had been coming into view, and we saw Cassiopeia and Perseus gradually rise above the horizon with great brilliancy. Apart from the scenery of the heavens, the sea

was beautifully phosphorescent. When the phosphorescence was stirred all the sparks were converted by the action of the retina into lines of light, which played around the ship in radial streamers.

"No time was lost by the astronomical party when they had once effected a landing on Eclipse Island, as we christened the point of observation. The islet was soon converted into a bustling little canvas town. From nearly every tent some instrument peered, all pointing in the one direction, as though these mortals, with their puny optics, thought to stare out of countenance the great Eye of Day. The Victorian party had two analysing spectroscopes and an integrating spectroscope, both equatorially mounted. The first was in the hands of Mr. Ellery, and the second was to be worked by Mr. Foord, both gentlemen having assistants to use the finding telescopes attached to pick out portions of the corona for examination. The two analysing spectroscopes were for examining the nature of the light of the chromosphere and the corona; and the integrating spectroscope, entrusted to Mr. McGeorge, was designed to examine the nature of the whole light, all the observations being directed with a view to determining the character of the orb from which the light proceeds. Prof. Wilson had two Savart's polariscopes. The object of polariscopic observations is to ascertain whether the light of the corona is that of a self-luminous body or a reflected light; also, in the case of its being a reflected light, to determine the angle of incidence, the great question to be settled being whether the corona is an appendage of the sun, or whether it exists in our atmosphere. There was also a magnetic theodolite to record magnetic disturbances. Mr. Moerlin, assisted by Mr. Walter, had charge of the photographic department. The principal instrument was one of Dallmeyer's rapid rectilinear lenses of 4 in. aperture and 30 in. focal length, giving an image of about three-tenths of an inch in diameter, equatorially mounted, and driven by clockwork. It was intended to take ten views during the totality. Mr. White, assisted by Mr. Black, directed the instrument's for determining the position of the station and predicting the time of the different phases of the eclipse. On the morning of the 7th December a brick pier to support the transit instruments was built. The pier was made square, as the instruments had to be placed not only in the meridian for the accurate determination of the time and longitude, but also at right angles to the meridian for finding the altitude. The first observations were made by an eight-inch altazimuth, which does not require such a massive stand as the transit. This gave very nearly the local time and the direction of the meridian. By means of these data the transit was fixed at right angles to the meridian, the finding of the latitude by this method being more troublesome and requiring finer weather than the finding of the time. On the first night the sky was rather cloudy, so that only two complete observations could be taken. The next night three observations were obtained, and the third night four observations were made. This being considered sufficient for the latitude, the instrument was next morning placed in the meridian, but the weather was so unfavourable that no observations could be taken in that position, so that the altazimuth had to be resorted to for the time observations.

"The Sydney party were furnished with an equatorial telescope, made by Merz, of Munich, with 7 in. clear aperture and 10 ft. 4 in. focal length, mounted on the German plan. Attached to the telescope was an apparatus for taking photographs in the principal focus of the object glass; also a photographic lens and camera, by which a second series of photographs could be taken simultaneously, the photograph lenses having a 3 in. aperture and 30 in. focal length. There were, in addition, two small telescopes of 2 in. aperture, with a magnifying power of 20, mounted equatorially and driven by clockwork, and a third telescope of 3 in. aperture and 4 ft. 6 in. focal length. The party intended to take a double series of photographs, to make two independent drawings, and to make naked-eye drawings and observations. The duties were apportioned as follows:—Mr. Russell, the Government astronomer, was to take photographs with the large telescope; Mr. Beaufoy Merlin photographs with the camera, the Rev. W. Scott and Lieutenant Gowlan to make drawings with small telescope, and Mr. W. McDonnell to act as timekeeper. The passengers were furnished with diagrams, and each received instructions to pay special attention to some one particular portion of the phenomena. When the day of the eclipse arrived the instruments were all working admirably. There had been numerous rehearsals to secure the utmost economy of time, and all felt that nothing but clear weather was needed for success.

"On Monday afternoon, the 11th of December, for the first time since leaving Melbourne, the sky became seriously overcast. The clouds had been gathered in dense dark masses all the earlier part of the evening, and at ten o'clock at night there was an awful thunderstorm, which lasted over an hour. The glow of the lightning, which came down in sheets of flame, and the rattle and crash of the thunder which followed the flash instantly, were inexpressibly grand. It was something quite beyond the experience of any one on board. A portion of the astronomical party returned from the shore in the middle of the storm. While they were ascending the ship's side the lightning struck the iron rigging, leaped across from stanchion to stanchion in balls of fire, and broke off at the ropes depending from the dead-eyes with loud crackling noises before it reached the sea. The vessel was lit up from stem to stern with a blinding light, and those on deck could see nothing for some seconds after each flash. The party in the boat were so much affected in this way that some alarm prevailed at first. Each one thought he had been deprived of sight, and asked his neighbour how it was with him. Had we been in a wooden ship the consequences would in all probability have been serious. This storm unfortunately did not clear the atmosphere. Next morning, the day of the eclipse, every eye was turned heavenward. To our dismay there was not a speck of sky to be seen. At ten o'clock there were several breaks in the clouds, and the sun showed himself for a few seconds, but an hour and a half later all was dense cloud again. Things looked brightest at mid-day, when there seemed to be a possibility of a fine afternoon. Then dark clouds swept up from the horizon, and extinguished almost every hope. At two o'clock there was yet another chance, though a faint one. This was tantalising. Every interest centred in a few patches of sky and their relations to the neighbouring clouds. They were aggravating clouds of every imaginable form and variety—cirrus, stratus, cumulus, nimbus—all were there at various times of the day, assuming the most distressing shapes, but giving no promise of dissolving.

"The computation of the duration of the eclipse was found to be very accurate, the eclipse occurring, as near as could be judged, three or four seconds before the predicted time. The computation was as follows:—First contact, 1h. 15m. 6s.; commencement of totality, 2h. 42m. 23s.; end of totality, 2h. 45m. 49s.; last contact, 4h. 1m. 6s. At the time of the first contact there was scarcely a rift in the canopy of clouds. The sun was wholly obscured. A few seconds later a passing glimpse was obtained, showing that the encroachment of the dark body of the moon on the bottom edge of the sun's disc had begun. Then all was dark again, excepting a faint luminous spot indicating the radiant body's position. A sharp shower fell at this time, and the instruments exposed had to be covered up. A drizzling rain continued during the remainder of the afternoon. At the faintest indication of a break in the clouds the astronomers ran out of their tents, and endeavoured to take observations, but without any result. Seven minutes before the commencement of totality there was a gleam of light from the sun, but the phase of the eclipse could not be discerned. We caught a momentary glimpse of the silver sickle of the sun at the top, just before the full obscuration. Then darkness fell suddenly like a pall on the surrounding objects, and we knew that totality had begun. It was a strange weird light at first. The large billowy clouds assumed olive and purple tints, and then changed to an ashen hue. These colours were reflected in the sea with some variations of light green and copper. Men looked livid in the light, and everything around had a most unearthly appearance. The steamer at anchor showed with a wonderful distinctness; every line, spar, and bit of cordage stood out against the horizon with the sharpness of a highly-magnified stereoscopic picture. There was no total darkness, owing, probably, to the amount of light diffused in the clouds. During totality, newspaper print could be read without much difficulty. Nor was there any perceptible diminution in the temperature. The three minutes and a half seemed exceedingly short. We saw nothing of the corona beyond a brief glimpse of a luminous mark shining faintly through the vapours. Some said they detected a decided red tinge. The clouds turned black, the tints disappeared from the sea, and utter darkness seemed coming upon us, when a few rays of light played upon the edges of a great bank of clouds in the N.W., some of the grey tints of dawn appeared, and daylight came back with a rush, as from the lifting of a veil. A hawk which had been sailing about swept down into a bush on the island to roost as soon as totality began. When daylight returned, he was astonished to find himself within a few feet of forty or fifty men,

and flew off in wild alarm. Though daylight had returned, the sun was still hidden by the clouds. A minute later we faintly saw the re-appearance of the solar limb at the bottom like a fine luminous thread, when more clouds interposed and shut out the great luminary for the remainder of the afternoon. This was all that was vouchsafed to us of the grand phenomena of a total solar eclipse. Never was Nature more assiduously wooed to reveal her treasures to science. But it was all to no purpose. Of the upward and onward march of the moon, the successive disappearance of the solar spots, the brilliant breaking into view of Bailey's Beads, the passage of the shadow through the air, the rose-coloured prominences and coronal radiations during totality, the reappearance of the solar crescent, and the final retreat of the lunar shadow into space, we had seen nothing. No observation could be taken by instrument. Mr. Russell exposed a photographic plate for twenty seconds during totality, but got no result.

"Nothing remained but to pack up and head the ship for home. The work was commenced before the eclipse was over, the rain falling dismally all the time, and was completed in less than three hours. The disappointment to all was very great. It was especially felt by the astronomical party, but they bore it bravely, as became men who had faithfully performed their duty. When, over desert that evening Mr. Ellery proposed in the interests of science, "Success to the Other Eclipse Expeditions," there was not one who did not cordially wish that all the other observers might have presented to their view the radiant globe projected on an azure sky, instead of the mountains of dull cloud that desolated our hopes.

"Later in the evening the schooner *Matilda*, bound for Sydney, from Torres Strait, with twelve tons of pearl shell, came alongside. The master and first officer reported having seen the eclipse very distinctly while near Night Island, in lat. 13° 9' S., long. 143° 39' E., about 15 miles from No. VI. island. They were not aware that the eclipse was going to occur, and at first took the darkness for approaching bad weather, until one of them happening to look under the mainsail, observed the phenomenon. Though wholly unprepared for the eclipse, they gave a very intelligent account of it, on being carefully examined by Prof. Wilson. Mr. Walton, master of the *Matilda*, stated that he had just ordered some clothes that were drying to be taken down, as bad weather seemed to be coming on, when he happened to look up and see the eclipse. It was so dark that he had to light the binnacle lamp. On a diagram being handed to him, he correctly indicated the points of disappearance and first reappearance of the sun. He drew on a black disc a line showing the boundary of the ring of light round the dark body of the moon, narrower in the right-hand bottom quadrant, and wider, with a projection, in the left-hand top quadrant. The colour of the light, he said, was whitish, like ordinary sunlight. He was particularly asked if he saw any pink light, and said no. He described the boundary as being sharp, and clear towards the moon, but rough and irregular outwards. The breadth of the annulus which he drew was about 1-16th of the diameter of the black disc. He said he and the other officers differed as to the duration of the darkness. The time was variously guessed at from five to ten minutes. His own opinion was that it was seven or eight minutes. There were no clouds on the sun at the time, and the blue sky was visible. Some of the South Sea Islanders on board were very much alarmed, and wept plentifully. Mr. Hore, first officer of the *Matilda*, stated that on his attention being directed to the eclipse, he went below to fetch his sextant in order to use the dark glasses. The captain called to him to make haste, as he was losing the best of it. On coming on deck he saw the dark body of the moon, surrounded by a fine ring of red light, outside of which was a broader ring of paler red light; while all outside of that was as black as night. His drawing on the card showed the breadth of the inner ring to be one-eighth the diameter of the moon, and the breadth of the outer on to be seven-sixteenths of the diameter of the moon. On being pressed as to the colour, he said it was not like fire itself, but like the glow of fire when the fire is concealed. The illustration he used was the glow of a house on fire seen from behind another house. Only one cloud passed over the sun during the eclipse, and that was a very small one. Peter R. Cooper, carpenter on board the *Matilda*, drew a line showing the boundaries of the inner and outer annuli, the inner one extending rather more than half round, the point of first reappearance being the middle of it, the outer one extending less than a

quadrant, and being entirely on the upper right-hand side. He described the colour as being like the upper ground part of a kerosene lamp shade in the cabin to which he pointed. The sun looked watery. When he first saw it it was coming from behind sand. There was no sky which could be called blue. It was a whitey sky. Cooper's drawing was marked with radial lines extending across the outer annulus from the inner.

"The return voyage was begun at daylight on the morning of the 13th of December. The only lasting traces of the astronomers left on the island were the photographers' dark rooms and the brick foundations used for the instruments, in which were entombed two bottles containing coins and newspapers and some particulars of the expedition. A member of the party, animated by something of the spirit of Old Mortality in his desire to preserve from oblivion the mortuary memorials of the expedition, inscribed this touching record on the slab which formed the top of one of these pedestals:—'Sacred to the memory of the Australian Eclipse Expedition.'"

SOCIETIES AND ACADEMIES

LONDON

Royal Society, February 15.—"On the Induction of Electric Currents in an Infinite plane sheet of uniformly conducting matter," by Prof. Clerk Maxwell, F.R.S.

The currents are supposed to be induced in the sheet by the variation in position or intensity of any system of magnets or electromagnets.

When any system of currents is excited in the sheet, and then left to itself, it gradually decays, on account of the resistance of the sheet. At any point on the positive side of the sheet, the electromagnetic action is precisely the same as if the sheet, with its currents, retaining their original intensity, had been carried away in the negative direction with a constant velocity R , where R is the value, in electromagnetic measure, of the resistance of a rectangular portion of the sheet, of length 1 and breadth 2π . This velocity, for a sheet of copper of best quality of one millimetre thickness, is about twenty-five metres per second, and is, therefore, in general comparable with the velocities attainable in experiments with rotating apparatus.

When an electromagnet is suddenly excited on the positive side of the sheet, a system of currents is induced in the sheet, the effect of which on any point on the negative side is, at the first instant, such as exactly to neutralise the effect of the magnet itself. The effect of the decay of this system of currents is therefore equivalent to that of an image of the magnet, equal and opposite to the real magnet, from the position of the real magnet, in the direction of the normal drawn away from the sheet, with the constant velocity R .

When any change occurs in an electromagnetic system, whether by its motion or by the variation of its intensity, we may conceive the change to take place by the superposition of an imaginary system upon the original system; the imaginary system being equivalent to the difference between the original and the final state of the system.

The current's excited in the sheet by this change will gradually decay, and their effect will be equivalent to that of the imaginary system carried away from the sheet with the constant velocity R .

When a magnet or electro-magnet moves or varies in any continuous manner, a succession of imaginary magnetic systems like those already described is formed, and each, as it is formed, begins to move away from the sheet with the constant velocity R . In this way a train or trail of images, is formed, moves off, parallel to itself, away from the sheet, as the smoke of a steamer ascends in still air from the moving funnel.

When the sheet itself is in motion, the currents, relatively to the sheet, are the same as if the sheet had been at rest, and the magnets had moved with the same relative velocity. The only difference is, that whereas when the sheet is at rest no difference of electric potential is produced in different parts of the sheet, differences of potential, which may be detected by fixed electrodes are produced in the moving sheet.

The problem of Arago's whirling disc has been investigated by MM. Félizi and Jochmann. Neither of these writers, however, has solved the problem so as to take into account the mutual induction of the currents in the disc. This is the principal step made in this paper, and it is expressed in terms of the theory of images, by which Sir W. Thomson solved so many problems in Static Electricity. In the case of the whirling disc, the trail

of images has the form of a helix, moving away from the disc with velocity R , while it revolves about the axis along with the disc. Besides the dragging action which the disc exerts on the magnetic pole in the tangential direction, parallel to the motion of the disc, the theory also indicates a repulsive action directed away from the disc, and an attraction towards the axis of the disc, provided the pole is not placed very near the edge of the disc, a case not included in the investigation. These phenomena were observed experimentally by Arago, *Ann. de Chimie*, 1826.

February 22.—"On a New Hygrometer." By Mr. Wildman O. Whitehouse.

"On the Contact of Surfaces." By William Spottiswoode, M.A., Treas. R.S.

In a paper published in the "Philosophical Transactions" (1870, p. 289), I have considered the contact, at a point P , of two curves which are co-planar sections of two surfaces (U , V); and have examined somewhat in detail the case where one of the curves, viz., the section of V , is a conic. In the method there employed, the conditions that the point P should be sextactic, involved the azimuth of the plane of section measured about an axis passing through P ; and consequently, regarded as an equation in the azimuth, it showed that the point would be sextactic for certain definite sections. It does not, however, follow, if conics having six-pointic contact with the surface U be drawn in the planes so determined, that a single quadric surface can be made to pass through them all. The investigation therefore of the memoir above quoted was not directly concerned with the contact of surfaces, although it may be considered as dealing with a problem intermediate to the contact of plane curves and that of surfaces.

In the present investigation I have considered a point P common to the two surfaces, U and V ; an axis drawn arbitrarily through P ; and a plane of section passing through the axis and capable of revolution about it. Proceeding as in the former memoir, and forming the equations for contact of various degrees, and finally by rendering them independent of the azimuth, we obtain the conditions for contact for all positions of the cutting plane about the axis. Such contact is called circumaxial; and in particular it is called uniaxial, biaxial, &c., according as it subsists for one, two, &c. axes. If it holds for all axes through the point it is called superficial contact; and in the memoir some theorems are established relating to the number of sections along which contact of a given degree must subsist in order to ensure uniaxial contact, as well as to the connection between uniaxial and multiaxial contact. At the conclusion of sec. 3 it is shown that the method of plane sections may, in the cases possessing most interest and importance, be replaced by the more general method of curved sections.

In the concluding section a few general considerations are given relating to the determination of surfaces having superficial contact of various degrees with given surfaces; and at the same time have indicated how very much the general theory is affected by the particular circumstances of each case. The question of a quadric having four-pointic superficial contact with a given surface is considered more in detail; and it is shown how in general such a quadric degenerates into the tangent plane taken twice. To this there is an apparently exceptional case, the condition for which is given and reduced to a comparatively simple form; but I must admit to having so left it, in the hope of giving a fuller discussion of it on a future occasion.

The subject of three-pointic superficial contact was considered by Dupin, "Développements de Géométrie," p. 12, and, as I have learnt since the memoir was written, a general theorem connecting superficial contact and contact along various branches of the curve of intersection of two surfaces (substantially the same as that given in the text) was enunciated by M. Moutard.

In a corollary to this theorem, M. Moutard states that through every point of a surface there can be drawn twenty-seven conics, having six-pointic contact with the surface. This number is perhaps open to question; and I have even reason to think, from considerations stated to me by Mr. Clifford, that the number ten, given in my memoir above quoted, may be capable of reduction by unity to nine. But this question refers to the subject of that earlier memoir rather than to this.

Geological Society, February 7.—Mr. Prestwich, F.R.S., president, in the chair. 1. "Further Notes on the Geology of the neighbourhood of Malaga," by M. D. M. d'Orteta. In this paper, which is a continuation of a former note laid

* Poncelet, "Applications d'Analyse à la Géométrie," 1864, tom. ii. p. 363

before the society (see Q. J. G. S. xxvii., p. 109), the author commenced by stating that his former opinion as to the Jurassic age of the rocks of Antequera is fully borne out by later researches upon their fossils. They apparently belong to the Portlandian series. The author made considerable additions to his description of the Torcal, near the foot of which he has found a sandstone containing abundance of *Gryphaea virgula* and *Ostrea deltoidea*. This he regards as equivalent to the Kimmeridge clay. In the Torcal he has also found a soft, white, calcareous deposit, overlying the limestones of supposed Portlandian age, and containing a fossil which he identifies with the Tithonian *Terebratulina diploya*. The author discussed the peculiar forms assumed by the rocks of the Torcal under denudation, which he supposed to be due originally to the upheaval caused by the rising of a great mass of greenstone, portions of which are visible at the surface on both sides of the range. 2. "On the River-courses of England and Wales," by Prof. A. C. Ramsay, F.R.S., The author commenced by describing the changes in the physical conformation of Britain during the Jurassic and Cretaceous periods, and the relations which the deposits found during those periods bore to the Palæozoic rocks of Wales and the north-west of England. He stated that the Miocene period of Europe was essentially a continental one, and that it was closed by important disturbances of strata in central Europe, one effect of which would be to give the secondary formations of France and Britain a slight tilt towards the north-west. To this he ascribed the north-westerly direction of many of the rivers of France; and he surmised that at this period the rivers of the middle and south of England also took a westerly course. The westerly slope of the cretaceous strata of England was also, he considered, the cause of the southern flow of the Severn, between the hilly land of Wales and the long slope of chalk rising towards the east. The Severn would thus establish the commencement of the escarpment of the chalk, which has since receded far eastward. The author believed that after the Severn had cut out its valley the cretaceous and other strata were gradually tilted eastwards, causing the easterly course of the Thames and other rivers of southern and eastern England. In these and other cases adduced by the author, the sources of these rivers were originally upon the chalk near its escarpment; and it is by the recession of the latter (which was followed by the formation of the oolitic escarpment) that its present relation to the river-courses has been brought about. The author also referred to the courses followed by the rivers of the more northern part of England, and indicated their relations to the general dip of the strata.

Geological Society, February 16.—Mr. Joseph Prestwich, F.R.S., president, in the chair.—The Secretary read the reports of the council, of the Library and Museum Committee, and of the auditors. The general position of the society was described as satisfactory, although, owing to the number of deaths which had taken place among the Fellows during the year 1871, the society did not show the same increase which has characterised former years. In presenting the Wollaston gold medal to the Secretary, Mr. David Forbes, for transmission to Prof. Dana, of Yale College, Connecticut, the President said:—"I have the pleasure to announce that the Wollaston Medal has been conferred on Prof. Dana, of Yale College, Newhaven, U.S.; and in handing it to you for transmission to our Foreign Member, I beg to express the great gratification it affords me that the award of the Council has fallen on so distinguished and veteran a geologist. Prof. Dana's works have a world-wide reputation. Few branches of geology but have received his attention. An able naturalist and a skilful mineralogist, he has studied our science with advantages of which few of us can boast. His contributions to our science embrace cosmical questions of primary importance—palæontological questions of special interest—recent phenomena in their bearings on geology, and mineralogical investigations so essential to the right study of rocks, especially of volcanic phenomena. The wide range of knowledge he brought to bear in the production of his excellent treatise on Geology, one of the best of our class books, embracing the elements as well as the principles of geology. His treatise on Mineralogy exhibits a like skill in arrangement and knowledge in selection. In conveying this testimonial of the high estimation in which we hold his researches to Prof. Dana, may I beg also that it may be accompanied by an expression how strongly we feel that the bonds of friendship and brotherhood are connected amongst all civilised nations of the world by the one common, the one universal, and the one

kindred pursuit of truth in the various branches of science."—Mr. David Forbes, in reply, said that it was to him a great pleasure to have, in the name of Prof. Dana, to return thanks to the society for their highest honour, and for this mark of the appreciation in which his labours are held in England. It had rarely if ever occurred in the history of the society that the Wollaston medal had been awarded to any geologist who had made himself so well known in such widely different departments of the science, for not only was Prof. Dana pre-eminent as a mineralogist, but his numerous memoirs on the Crustaceans, Zoophytes, coral islands, volcanic formations, and other allied subjects, as well as his admirable treatise on general Geology, fully testify to the extensive range and great depth of his scientific researches.—The President then presented the balance of the proceeds of the Wollaston donation fund to Prof. Ramsay, F.R.S., for transmission to Mr. James Coll, and addressed him as follows:—"The Wollaston fund has been awarded to Mr. James Coll, of Edinburgh, for his many valuable researches on the glacial phenomena of Scotland, and to aid in the prosecution of the same. Mr. Coll is also well known to all of us by his investigation of oceanic currents and their bearings on geological questions, and of many questions of great theoretical interest connected with some of the great problems in Geology. Will you, Prof. Ramsay, in handing this token of the interest with which we follow his researches, inform Mr. Coll of the additional value his labours have in our estimation, from the difficulties under which they have been pursued, and the limited time and opportunities he has had at his command."—Prof. Ramsay thanked the president and council in the name of Mr. Coll for the honour bestowed on him. He remarked that Mr. Coll's merits as an original thinker are of a very high kind, and that he is all the more deserving of this honour from the circumstance that he has risen to have a well-recognised place among men of science without any of the advantages of early scientific training; and the position he now occupies has been won by his own unassisted exertions. The President then proceeded to read his Anniversary Address, in which he discussed the bearings upon theoretical Geology of the results obtained by the Royal Commission on Water-Supply and the Royal Coal Commission. The Address was prefaced by biographical notices of deceased Fellows, including Sir Roderick I. Murchison, Mr. William Lonsdale, Sir Thomas Acland, Sir John Herschel, Mr. George Grote, Mr. Robert Chambers, and M. Lartet.—The ballot for the Council and Officers was taken, and the following were duly elected for the ensuing year:—President—The Duke of Argyll, K.T., F.R.S. Vice-Presidents—Prof. P. Martin Duncan, F.R.S., Prof. A. C. Ramsay, F.R.S., Warrington W. Smyth, F.R.S., Prof. John Morris. Secretaries—John Evans, F.R.S., David Forbes, F.R.S. Foreign Secretary, Prof. T. D. Ansted, F.R.S. Treasurer—J. Gwyn Jeffreys, F.R.S. Council—Prof. T. D. Ansted, F.R.S., the Duke of Argyll, F.R.S., W. Carruthers, F.R.S., W. Boyd Dawkins, F.R.S., Prof. P. Martin Duncan, F.R.S., R. Etheridge, F.R.S., John Evans, F.R.S., James Fergusson, F.R.S., J. Wickham Flower, David Forbes, F.R.S., Capt. Douglas Galton, C.B., F.R.S., Rev. John Gunn, M.A., J. Whitaker Hulke, F.R.S., J. Gwyn Jeffreys, F.R.S., Sir Charles Lyell, Bart., F.R.S., C. J. Meyer, Prof. John Morris, Joseph Prestwich, F.R.S., Prof. A. C. Ramsay, F.R.S., R. H. Scott, F.R.S., W. W. Smyth, F.R.S., Prof. J. Tennant, Henry Woodward.

Zoological Society, February 20, Prof. Flower, F.R.S., in the chair.—The secretary read a report on the additions that had been made to the society's menagerie during the month of January, 1872, and called particular attention to a young king penguin (*Apelodytes pennanti*), presented by Mr. F. P. Cobb, of Port Stanley, Falkland Islands, and to a collection of African land tortoises, transmitted by Dr. Grey of Cradock, Cape Colony.—The secretary also called attention to the female Sumatran rhinoceros (*Rhinoceros sumatrensis*) just added to the society's menagerie.—A paper was read by Mr. J. W. Clark, on the visceral anatomy of the hippopotamus, as observed in the young specimen of this animal which had died in the society's gardens on the 10th January, 1872. After giving an account of the morbid appearances noticed, Mr. Clark described in detail the stomach of this specimen, which appeared to differ in some points from those examined by previous authorities.—A communication was read from Dr. J. S. Bowerbank, F.R.S., containing the second part of his "Contributions to a General History of the Spongiadae," in which was contained a full account of two species of the genus *Geodia*.—A paper by the

Rev. O. P. Cambridge was read, "On the Spiders of Palestine and Syria," in which was given a general list of the Araneidea of those countries, together with descriptions of numerous new species, and the characters of two new genera.—A communication was read from Dr. John Anderson, containing descriptions of some Persian, Himalayan, and other reptiles, either new or little known to science. A second paper by Dr. Anderson contained some further remarks on the external characters of the new Borneo macaque, which he had recently described under the name *Macacus brunneus*.—A communication was read from Count Tommaso Salvadori, containing a note on a specimen of Lidth's jay (*Garrulus lidthii*), in the collection of the King of Italy, which had originally been received alive from Japan. Mr. D. G. Elliot read a note on a Cat described by Dr. Gray in the Proceedings of the Zoological Society for 1867, as *Felis pardinae* from India, which Mr. Elliot considered to be identical with *Felis Geoffroyi* of S. America.

MANCHESTER

Literary and Philosophical Society, February 6.—E. W. Binney, F.R.S., president, in the chair. Dr. Joule, F.R.S., called attention to the very extraordinary magnetic disturbances on the afternoon of the 4th instant, and from which he anticipated the aurora which afterwards took place. The horizontally suspended needle was pretty steady in the forenoon of that day, but about 4 P.M. the north end was deflected strongly to the east of the magnetic meridian, and afterwards still more strongly to the west. The following were the observations made:—

Time	Deflection from the Magnetic Meridian.	Time	Deflection from the Magnetic Meridian.
4.0 P.M.	0 50 E.	6.10 P.M.	1 24 W.
4.30 "	0 47 W.	6.12 "	1 8 "
4.55 "	0 22 "	7.41 "	0 10 "
4.58 "	3 0 "	7.43 "	0 0 "
5.9 "	3 45 "	8.9 "	0 42 "
5.12 "	0 52 "	8.31 "	0 10 "
5.23 "	5 36 "	8.54 "	1 18 "
5.24 "	2 28 "	8.58 "	0 52 "
5.35 "	0 52 "	11.3 "	0 5 "
5.55 "	0 52 "		

Mr. Sidebotham states that he also expected the magnificent aurora on account of the violent disturbance of the needle at Bowdon, amounting to at least 3°. Observation with the spectroscope by Dr. Joule showed a bright and almost colourless line near the yellow part of the spectrum. This line appeared in whatever part of the heavens the instrument was directed, and could be plainly seen when the sky was covered with clouds and rain was falling. When looking at the most brilliant red light of the aurora a faint red light was seen at the red end of the spectrum, and beyond the bright white line, towards the violet end, two broad bands of faint white light. Mr. Thomas Harrison stated that he saw the aurora on last Sunday evening from 6^h 15^m to 9^h 30^m and took spectroscopic observations thereon from various parts of the sky. In each case, however, he discovered only one bright yellow line, situated between D and E, being on Kirchhoff's scale about 1255 to 1260. He is not acquainted with any known substance that gives a corresponding line. The line throughout was very clear and decided, both in the narrow and wide slit; but he failed to discover any continuous spectrum. The line was also very perceptible by reflection from those parts of the sky in which no trace of aurora was visible; and although the streaks were both red and white, the spectroscope appeared to give the aurora as a monochromatic light.

KILKENNY

Royal Historical and Archaeological Association of Ireland, January 17.—The Mayor of Kilkenny in the chair. Rev. J. Graves (hon. sec.) read the report for 1871. The following members were elected:—Earl of Dunraven, Rev. W. H. Fraser, L. Daniel, J. Lloyd, G. Reade, W. Irvine, J. Martin, W. J. Lemon, A. Gibb, A. Menzies, F. Barton, and W. Moore; the Rev. Dean Watson and B. Delany, were raised to Fellows;—"Historical Documents of 1614" were exhibited by the hon. sec., one of which contained a key to the cipher used in the correspondence between Ormonde and the confederate leaders at the time. The following papers were read:—"On a recent discovery of Coins at Mullaboden, Ballymore Eustace, co. Kildare," by Rev. J. F. Shearman; "On Kilkenny, past and present," by P. Waters; "On some Unrecorded Antiquities in Yar-Connaught," by G. H. Kianhan; "On some Antiquities of Oak at Bellisle, co. Fermanagh," by W. F. Wakeman.

THURSDAY, MARCH 7, 1872

A FRENCH ASSOCIATION FOR THE
ADVANCEMENT OF SCIENCE

IN France there is at the present time a movement of regeneration in the scientific world, slow indeed, and difficult to be seen through the troubles on the surface, but the evidence of it is incontestable. The actual activity is great; publications of every kind appear, some quite new, as the *Journal de Physique*, the *Archives de Zoologie*; others improved and extended, as the *Annales de l'Ecole Normale*. The *Comptes Rendus* of the Paris Academy, which are the weekly *résumé* of French science, have rarely been so full of important memoirs, while research, almost dead to England, promises regeneration for French science.

To take a recent example of this activity, we may cite about fifty notices relative to the aurora borealis of last month, coming from every part of France. This amount of attention paid to a phenomenon which, a few years ago, would have excited nothing more than a mere curiosity, evidences the actual aspirations connected with, and a natural taste for, scientific subjects. But what must specially strike the English scientific world is the recent foundation of a French Association for the Advancement of Science, on the model of the British Association, without any other modifications than those which must result from the different characters of the two nations.

Though this proposal has not reached its complete extension (no publicity having been as yet given to it) it is possible, from the rapidity with which the working committee was constituted, the large amount of money collected, and the sympathies expressed on all sides, to predict for the younger sister of the British Association a great success.

The proposed statutes, which have been drawn up and provisionally adopted at a series of meetings at which MM. Balard, Berthelot, Briot, Broca, Claude Bernard, Combes, Cornu, Decaisne, Delaunay, Descloiseaux, De Luynes, Dumas, Friedel, P. Gervais, A. Girard, G. Hachette, Lacaze-Duthiers, Laugier, Levasseur, Loewy, Marié-Davy, V. Masson, Pasteur, Serret, Tisserand, and Wurtz were present, are as follows:—

ART. I.—The Association proposes to favour by every means in its power the progress of the sciences, their practical application, and the diffusion of scientific knowledge. For this purpose it will exercise its influence principally by meetings, conferences, and publications; by gifts of instruments or money to persons engaged in researches, observations, or experiments, scientific enterprises which it would have approved or provoked. It appeals to all those who consider the culture of the sciences as necessary to the greatness and prosperity of France.

ART. II.—The Association is established with a capital divided into shares of 500 francs each, subscribed by members who take the title of founders. It will commence its operations as soon as 200 of these shares, forming a capital of 100,000 francs, shall have been subscribed.*

ART. III.—The Association shall consist of founders and ordinary associates, who shall pay an annual subscription of

20 francs. This subscription can always be compounded by the payment of the sum of 200 francs once for all.

ART. IV.—The number of founders or associates is unlimited, and all enjoy the same privileges. The names of the founders shall, however, always appear at the head of the lists, and these members receive gratuitously and for ever all the publications of the Association, as many copies as they have subscribed shares of 500fr.

ART. V.—The seat of the Council of the Association shall be at Paris.

ART. VI.—Each year the Association shall hold in one of the towns of France a general session, the duration of which shall be eight days.

ART. VII.—In the general session the Association shall be divided into sections, of which the number and functions shall be fixed by the general assembly on the proposition of the Council. These sections shall be attached to the four groups of Mathematical, Physical and Chemical, Natural, and Economical and Statistical science. Every member of the Association shall choose each year the section to which he wishes to belong. He can nevertheless take part in the work of the other sections, but only with consultative voice (*voix consultative*.)

ART. VIII.—The bureau of the Association is composed:—1, of the president and secretary; 2, of the presidents and secretaries of sections; 3, of the treasurer and the librarian.

ART. IX.—The Association shall be managed gratuitously by a Council composed—1, of the bureau of the association; 2, of members elected in the general assembly to the number of three by each section.

ART. X.—At the commencement of each session the presidents, vice-presidents, and secretaries of the sections are nominated directly by a relative majority of the sections.

At the end of each session, the Association, united in general assembly, shall name the town where the following session shall take place, fix a programme for that session, and nominate by relative majority the president and secretary for the following year, and also the members of the Council.

The president and secretary shall be taken in turn from each of the four sections. If either is prevented from attending, he shall be replaced by one of the presidents or secretaries of the divisions of the section to which he may belong.

ART. XI.—The Council charged with the organisation of the session in the town selected can for that purpose elect an honorary president.

ART. XII.—All members of the Association are asked to take part in elections by voting either in person or by letter (*par correspondance*).

ART. XIII.—The Council represents the Association. It has full power to carry on and administer the social business, both active and passive. It shall receive all funds belonging to the Association, of whatever kind they may be. It shall invest in Government securities the funds arising from the shares subscribed by the founders, and from the compounding of annual subscriptions by the associates. It shall superintend the expenditure of the disposable funds voted by the Association on its proposal. It shall make all rules necessary for maintaining internal order and the execution of the present statutes. It shall convocate the Association, and arrange the programme of the meeting, in conformity with deliberations made in the general assembly.

The Council shall nominate and constitute the special committees for the funds for encouragements, for publications, and for conferences.

The Council shall deliberate in due form and by the majority of members present; nevertheless no resolution shall be valid unless it shall have been deliberated upon in the presence of one-fourth, at least, of the members of the Council.

ART. XIV.—The Council shall prepare annually the budget of expenses of the Association, and shall read in the annual general session a detailed account of receipts and expenses of work themselves (*de l'œuvre et du coût*).

ART. XV.—The statutes can be modified on the proposition of the Council, and by a majority of two-thirds voting in the general assembly. The proposed modifications shall be indicated beforehand in the Convocatory letters addressed to all members of the Association.

PROPOSED SECTIONS

1st Section—Mathematical Science

1st, Division of Mathematics, Astronomy, and Geodetical

* This amount has been exceeded some weeks since. It was subscribed by scientific men, and by the greater number of the councils of the railway, industrial, and financial companies.

Science; 2nd, Mechanics; 3rd, Navigation; 4th, Civil and Military Engineering.

2nd Section—*Chemical and Physical Science*

5th, Physics; 6th, Chemistry; 7th, Meteorology and Physics of the Globe.

3rd Section—*Natural Sciences*

8th, Zoology and Zootechny; 9th, Botany; 10th, Geology and Mineralogy; 11th, Medicine.

4th Section—*Economic Sciences*

12th, Agriculture (*Agronomie*); 13th, Ethnography and Geography; 14th, Statistics.

We are told that certain modifications may be introduced before the final constitution of the Association, but they are not likely to change the general character of the institution.

Amongst the promoters of this Association are to be found the names most celebrated in French science, showing that this scientific movement is a general one, and answers to a pressing want.

A peculiar feature will be remarked: the general spirit of the statutes denotes a very decided tendency to *decentralisation*. Up to the present time French science has had the reverse tendency,—to attract to Paris all the intelligent strength of the nation. The result, most excellent for Paris, which constitutes one of the greatest scientific centres in the world, has been very disadvantageous for the country. The provincial *facultés* (local universities) have been deprived of the most important of their members, and are actually very far from answering to the scientific standard of the metropolis. If we add now that the *Ministère de l'Instruction Publique* not only has insufficient funds for these institutions of higher instruction, but considers the *facultés* as sources of revenue by the granting of degrees, it will be understood that it is the right time to act vigorously to raise the taste for science in the parts of the country remote from the capital.

Too much encouragement cannot be given to the founders of the French Association in their task of decentralising science in France. The first result will be to create real scientific centres, vigorous with a new life, and diffusing a great activity. It cannot be objected that the genius of the nation is opposed to such a decentralisation, and that all aspirations must necessarily converge towards Paris. This is an error. The town of Montpellier gives the example of a *Faculté de Médecine*, of which the reputation is scarcely inferior to the Paris *faculté*. It is equally certain that Toulouse the town of *Jeux floraux*, Lyons, Marseilles, Clermont, and many others, under a vigorous impulse, could also become great scientific centres. To aim at this object, nothing will be better than to show every year the whole scientific corps of Paris, the scientific *Etat-major* transporting itself to a remote city or town, liberally giving lectures and conferences, and promoting researches and experiments. Thus the metropolis will greatly help the scientific renovation, and will show that it wishes not to attract to itself the whole force and consideration, but to diffuse its own energy over the whole country.

It is probable that the first meeting will be held this year at Lyons, the second town of France, at the end of August or the beginning of September. To the interest of the meeting would be added the attraction of a great industrial exhibition.

We cannot do otherwise than wish a great success to the French Association. We are happy to see that all parties are uniting in their exertions in such a direction; that a good number of associates, independent or belonging to scientific societies, are giving in their adhesion to the new association. Amongst the congratulations which the Association ought to receive at its birth, no doubt one of the first will be addressed by the British Association. This will be for England both a duty and an honour. A nation must always be happy to be valued and proud to be imitated.

QUETELET'S CONTRIBUTIONS TO THE
SCIENCE OF MAN

Physique Sociale, ou Essai sur le Développement des Facultés de l'Homme. Par Ad. Quetelet. (Brussels, 1869.)

Anthropométrie, ou Mesure des différentes Facultés de l'Homme. Par Ad. Quetelet. (Brussels, 1870.)

TWO lines of research into the Science of Man, of the highest moment as well in theoretical Anthropology as in practical Ethics and Politics, both to be always associated with the name of Quetelet, are now discussed at large in his *Social Physics* and *Anthropometry*. The two great generalisations which the veteran Belgian astronomer has brought to bear on physiological and mental science, and which it is proposed to describe popularly here, may be briefly defined. First, he has been for many years the prime mover in introducing the doctrine that human actions, even those usually considered most arbitrary, are in fact subordinate to general laws of human nature; this doctrine, maintained in previous publications, especially in the earlier edition of the first-named work some thirty-seven years ago, is now put forth in its completest form. Second, he has succeeded in bringing the idea of a biological type or specific form, whether in bodily structure or mental faculty, to a distinct calculable conception, which is likely to impress on future arguments a definiteness not previously approached.

The doctrine of the regularity and causality of human actions was powerfully stated some fifteen years ago by Mr. Buckle in the introduction to his "History of Civilisation." Buckle is here essentially the exponent of Quetelet's evidence, from which, indeed, as a speculative philosopher he draws inferences more extreme than those of his statistical teacher. To Quetelet is due the argument from the astonishing regularity from year to year in the recurrences of murders and suicides, a regularity extending even to the means or instruments by which these violent acts are committed; his inference being broadly "that it is society which prepares the crime, the criminal being only the instrument which executes it." From various other sources Buckle brought together other pieces of evidence, especially one which is now quoted by all who discuss the subject, the regularity from year to year of letters posted, whose writers forget to direct them. It may by this time be taken as proved by such facts that each particular class of human actions may be estimated, and to a great extent even predicted, as a regular product of a definite social body under definite conditions. To quote another luminous instance of this regularity of

action, M. Quetelet gives a table of the ages of marriage in Belgium (*Phys. Soc. i. p. 275*). Here the numbers of what may be called normal marriages, those between men under 45 with women under 30, as well as of the less usual unions where the women are between 30 and 45, show the sort of general regularity which one would expect from mere consideration of the circumstances. The astonishing feature of the table is the regularity of the unusual marriages. Disregarding decimals, and calculating the approximate whole numbers in their proportion to 10,000 marriages, the table shows in each of five five-year periods from 1841 to 1865, 6 men aged from 30 to 45 who married women aged 60 or more, and 1 to 2 men aged 30 or less who married women aged 60 or more. M. Quetelet may well speak of this as the most curious and suggestive statistical document he has met with. These young husbands had their liberty of choice, yet their sexagenarian brides brought them up one after the other in periodical succession, as sacrifices to the occult tendencies of the social system. The statistician's comment is, "it is curious to see man, proudly entitling himself King of Nature and fancying himself controlling all things by his free-will, yet submitting, unknown to himself, more rigorously than any other being in creation, to the laws he is under subjection to. These laws are co-ordinated with such wisdom that they even escape his attention."

The admission of evidence like this, however, is not always followed by the same philosophical explanation of it. Buckle finds his solution by simply discarding the idea that human action "depends on some capricious and personal principle peculiar to each man, as free-will or the like;" on the contrary, he asserts "the great truth that the actions of men, being guided by their antecedents, are in reality never inconsistent, but, however capricious they may appear, only form part of one vast scheme of universal order, of which we, in the present state of knowledge, can barely see the outline." M. Quetelet's argument from the same evidence differs remarkably from this. His expedient for accounting for the regularity of social events without throwing over the notion of arbitrary action, is to admit the existence of free-will, but to confine its effects within very narrow bounds. He holds that arbitrary will does not act beyond the limits at which science begins, and that its effects, though apparently so great, may, if taken collectively, be reckoned as null, experience proving that individual wills are neutralised in the midst of general wills (p. 100). Free-will, though of sufficient power to prevent our predicting the actions of the individual, disappears in the collective action of large bodies of men, which results from general social laws, which can accordingly be predicted like other results regulated by natural laws. We may perhaps apprehend the meaning of Quetelet's views more clearly from another passage, where, to show how apparently isolated events may be really connected under some wide law, he compares single facts to a number of scattered points, which seem not related to one another till the observer, commanding a view of a series of them from a distance, loses sight of their little accidents of arrangement, and at the same time perceives that they are really arranged along a connecting curve. Then the writer goes on to imagine, still more suggestively, that these points might actually be tiny animated creatures, capable of free action within a

very narrow range, while nevertheless their spontaneous movements would not be discernible from a distance (p. 94), where only their laws of mutual relation would appear. M. Quetelet can thus conciliate received opinions by recognising the doctrine of arbitrary volition, while depriving it of its injurious power.* His defence of the existence of free-will is perhaps too much like the famous excuse of the personage who was blamed for going out shooting on the day he had received the news of his father's death, and who defended himself on the ground that he only shot very small birds. But it is evident that the statistics of social regularity have driven the popular notion of free-will into the narrow space included between Quetelet's restriction and Buckle's abolition of it. In fact, no one who studies the temper of our time will deny the increasing prevalence of the tendency of the scientific world to reject the use of the term free-will in its vulgar sense, that of unmotivated spontaneous election, and even to discourage its use in any other sense as apt to mislead, while its defenders draw their weapons not so much from observation of facts as from speculative and dogmatic philosophy.

To those who accept the extreme principle that similar men under similar circumstances must necessarily do similar acts; and to those, also, who adopt the notion of free-will as a small disturbing cause which disappears in the large result of social law, the regularity of civilised life carries its own explanation. Society is roughly homogeneous from year to year. Individuals are born, pass on through stage after stage of life, and die; but at each move one drops into another's place, and the shifting of individuals only brings change into the social system, so far as those great general causes have been at work which difference one age from another, the introduction of different knowledge, different principles, different arts, different industrial materials and outlets. The modern sociologist, whatever his metaphysical prepossessions, looks at society as a system amenable to direct cause and effect. To a great extent his accurate reckonings serve to give more force and point to the conclusions of rough experience; to a great extent, also, they correct old ideas and introduce new aspects of social law. What gives to the statistical method its greatest scope and power is that its evidence and proof of law applies indiscriminately to what we call physical, biological, and ethical products of society, these various effects acting and re-acting on one another. A few instances may be given to show the existence of the relations in question, without attempting to show their precise nature, nor to trace the operation of other determining causes.

Thus, for instance, the mode of life affects its length. Statistics show that the mortality of the very poor is about half as much again as the mortality of the very rich; while as to the influence of professions, it appears that in Germany only twenty-four doctors reach the age of seventy as against thirty-two military men and forty-two theologians. The propensity to theft bears a distinct relation to age; thus the French criminal statistics estimate the propensity to theft between the ages of twenty-one and twenty-five, as being five-thirds as much as between the ages of thirty-five and forty. The

* In regard to the relation of statistics to the doctrine of fatalism, see Dr. Farrer's "Report on the Programme of the Fourth Session of the Statistical Congress."

amount of criminality in a country bears a relation, indirect and as yet obscure, but unmistakeable, to its education, or rather, to its want of education. In France, in 1828-31, the constant percentage of accused persons was about as follows : could not read or write, sixty-one ; imperfectly, twenty-seven ; well, twelve. The comparison of this group of numbers with those taken lately in England shows a great change of proportion—evidently resulting from the wider diffusion of education ; but the limitation of crime to the less-educated classes is even more striking : cannot read or write, thirty-six ; imperfectly, sixty-one ; well, three. Again, for an example of connection of physical conditions with moral actions, we may notice a table, showing how the hours of the day influence people who hang themselves. (Phys. Soc. ii. 240.) The maximum of such cases, 135, occurred between six and eight in the morning ; the number decreased slightly till noon, and then suddenly dropped to the minimum ; there being 123 cases between ten and twelve o'clock, against only 32 between twelve and two o'clock. The number rose in the afternoon to 104 cases between four and six, dropping to an average of about 70 through the night, the second minimum, 45, being between two and four o'clock in the morning. Here it is impossible to mistake the influences of the periods of the day ; we can fancy we see the poor wretches rising in the morning to a life of which the misery is beyond bearing, or can only be borne till evening closes in ; while the temporary relief of the midnight sleep and the midday meal are marked in holding back the longing to self-destruction. Madness varies with the season of the year : the maximum being in summer, and the minimum in winter (p. 187) ; a state of things which seems intelligible enough. Again, it is well known in current opinion that more children are born in the night than in the day ; in fact, there are about five night-born against four day-born, the maximum being about midnight, the minimum a little before noon (i. p. 208). Why this is no one yet knows ; it is a case of unexplained law. But another not less curious law relating to births seems to have been at last successfully unravelled. In Europe about 106 boys are born to every 100 girls. The explanation appears to depend on the husband being older than the wife ; which difference again is regulated by prudential considerations, a man not marrying till he can maintain a wife. In connection with this argument it must be noticed that illegitimate births show a much less excess of male children (p. 168). Here, then (if this explanation may be accepted), it appears that a law which has been supposed to be due to purely physiological causes is traceable to an ultimate origin in political economy.

The examples brought forward by Quetelet, which thus show the intimate relation between biological and ethical phenomena, should be pondered by all who take an interest in that great movement of our time—the introduction of scientific evidence into problems over which theologians and moralists have long claimed exclusive jurisdiction. This scientific invasion consists mainly in application of exact evidence in place of inexact evidence, and of proof in place of sentiment and authority. Already the result of the introduction of statistics into inquiries of this kind appears in new adjustments of the frontier line between right and wrong, as measured under our modern

social conditions. Take, for instance, the case of founding hospitals, which provide a "tour," or other means for the secret reception of infants abandoned by their parents. It has seemed and still seems to many estimable persons an act of benevolence to found and maintain such institutions. But when their operation comes to be studied by statisticians, they are found to produce an enormous increase in the number of exposed illegitimate children (Phys. Soc. i. 384). In fact, thus to facilitate the safe and secret abandonment of children is to set a powerful engine at work to demoralise society. Here, then, a particular class of charitable actions has been removed, by the statistical study of its effects, from the category of virtuous into that of vicious actions. An even more important transition of the same kind is taking place in the estimation of almsgiving from the ethical point of view. Until modern ages, through all the countries of higher civilisation, men have been urged by their teachers of morality to give to the poor, worthy or unworthy ; the state of public opinion being well exemplified by the narrowing of the word "charity" from its original sense to denote the distribution of doles. Yet, when the statistics of pauperism were collected and studied, it was shown that indiscriminate almsgiving is an action rather evil than good, its tendency being not only to maintain, but actually to produce, idle and miserable paupers. In our time a large proportion of the public and private funds distributed among the poor is spent in actually diminishing their industry, frugality, and self-reliance. Yet the evil of indiscriminate almsgiving is diminishing under the influence of sounder knowledge of social laws, and genuine charity is more and more directed by careful study of the means by which wealth may be spent for the distinct benefit of society. Such examples as these show clearly the imperfection and untrustworthiness of traditional, or what is called intuitive morality, in deciding on questions of right and wrong, and the necessity of appealing in all cases to the best attainable information of social science to decide what actions are really for or against the general good, and are therefore to be classed as virtuous or vicious.

Moreover, it is not too much to say that the comparatively small advance which moral science has made since barbaric ages has been due to the repugnance of moralists to admit, in human action, the regular causality which is the admitted principle of other parts of the action of the universe. The idea of the influence of arbitrary will in the individual man has checked and opposed the calculations which now display the paramount action of society as an organised whole. One point in M. Quetelet's doctrine of society requires a mention for its practical bearing on morals. There has seemed to some to be an immoral tendency in his principle that virtuous and vicious acts are products, not merely of the individual who does them, but of the society in which they take place, as though the tendency of this view were to weaken individual responsibility, and to discourage individual effort. Yet, when properly understood, this principle offers a more strong and definite impulse to the effort of society for good and against evil, than the theory which refers the individual's action more exclusively to himself. M. Quetelet's inference from the regular production of a certain amount of crime year by year from

a society in a certain condition, is embodied in his maxim that society prepares the crime and the criminal executes it. This should be read with a comment of the author's. "If," he says, "I were to take up the pavement before my house, should I be astonished to hear in the morning that people had fallen and hurt themselves, and could I lay the blame on the sufferers, inasmuch as they were free to go there or elsewhere?" Thus every member of society who offers a facility to the commission of crime, or does not endeavour to hinder its commission, is, in a degree, responsible for it. It is absurd to suppose that the crimes in great cities are attributable altogether to the free agency of the poor wretches who are transported or hung for them. The nation which can and does not prevent the existence of a criminal class is responsible collectively for the evil done by this class. This we can see plainly enough, although the exact distribution of the responsibility among the different members of society may be impossible to determine. Such a theory, of course, casts aside the revenge-theory of criminal law, assimilating the treatment of criminals to the operation of a surgeon healing a diseased part of the body, if possible, or, if not, rendering it harmless or removing it.

The wealthy and educated classes, whose lives seem to themselves as free from moral blame as they are from

legal punishment, may at first hear with no pleasant surprise a theory which inculcates them as sharers in the crimes necessarily resulting from the state of society which they are influential in shaping. Yet this consideration is by no means one of mere hopeless regret, for coupled with it is the knowledge that it is in their power, by adopting certain educational and reformatory measures, so to alter the present moral status of society as to reduce the annual budget of crime to a fraction of its present amount. Thus the doctrine that the nation participates in and is responsible for the acts of its individual members is one which widens the range of duty to the utmost. The labours of M. Quetelet in reducing to absolute calculation this doctrine of the solidarity of human society, entitle him to a place among those great thinkers whose efforts perceptibly raise that society to a higher intellectual and moral level. Here, as everywhere, the larger comprehension of the laws of nature works for good and not for evil in the history of the world.

Some slight account has now to be given of M. Quetelet's doctrine of typical forms, as displayed in the "homme moyen," or "mean man," of a particular nation or race. This is no new theory; but since the publication of the "Physique Sociale" in 1835, the author has been at work extending and systematising it, his last results being shown in the present works. First, it must be

pointed out that the term "homme moyen" is not intended to indicate what would be popularly meant by an "average man." An average or arithmetical mean of a number of objects may be a mere imaginary entity, having no real representative. Thus, an average chess-man, computed as to height from the different pieces on the board, might not correspond to any one of the actual pieces. But the "homme moyen" or central type of a population really exists; more than this, the class he belongs to exceeds in number any other class, and the less nearly any other class approaches to his standard the less numerous that class is, the decrease in the number of individuals as they depart from the central type conforming to a calculable numerical law. The "mean man" (the term may probably be adopted in future researches; and when technically used its popular meaning will cease to interfere with this special one)—the "mean man" thus stands as a representative of the whole population, individuals as they differ from him being considered as forms varying from his specific type.

To realise a conception which even among anthropologists has scarcely yet become familiar, it is desirable to show by what actual observations M. Quetelet was led to the discovery of his principle. When a large number of men of a practically homogeneous population are measured, and arranged in groups accordingly, it becomes evident that the individuals are related to one another by a law of distribution. A central type is represented by the most numerous group, the adjoining groups becoming less and less numerous in both directions. Thus, on classifying the measured heights of some 26,000 American soldiers of the Northern army during the late war, the proportionate number of men to each height was ascertained to be as follows (Phys. Soc. i. p. 131; Anthropol. p. 259):—

Height, inches	60	61	62	63	64	65	66	67	68
No. of men in 1,000 . .	1	1	2	20	48	75	117	134	157
Height, inches	69	70	71	72	73	74	75	76	
No. of men in 1,000 . .	140	121	80	57	26	13	5	2	

Here it is seen that the mean man is a little under 5 ft. 8 in. in height, the numbers of men shorter and taller diminishing with evident regularity, down to the few representatives of the very short men of 5 ft. and under, and the very tall men of 6 ft. 4 in. and over. The law of relation of height to numerical strength is shown graphically by the binomial curve figured above, where the abscissæ (measured from an origin on the left) represent the heights of the men, and the ordinates the relative numbers of men corresponding to each height. The maximum ordinate, representing the number of mean men, is at m = about 5 ft. 8 in., the ordinates on both sides diminishing almost to nothing as they reach the dwarfish and gigantic limits d and g , and vanishing beyond.

Again, measurement round the chest, applied to the soldiers of the Potomac army, shows a similar law of grouping (Phys. Soc. ii. 59; Anthropol. p. 289).

Round chest, inches	28	29	30	31	32	33	34	35
No. of men in 1,000	1	3	11	36	67	119	160	204
Round chest, inches	36	37	38	39	40	41	42	
No. of men in 1,000	166	119	68	28	13	4	1	

Here the mean man measures about 35 in. round the chest, the numbers diminishing both ways till we reach the few

extremely narrow-chested men of 28in., and the few extremely broad-chested men of 42in. These two examples may represent the more symmetrical cases of distribution of individuals on both sides of a central type, as worked out by M. Quetelet from various physical measurements applied to large numbers of individuals. Here the tendency to vary is approximately equal in both directions. Where the tendency to vary is perceptibly different in the two directions the curve loses its symmetry, as in the figures representing the weights of women at different ages (Anthropom. p. 349), and the number of marriages of men and women at different ages (Phys. Soc. i. 272). The actual series of numbers given by observation are placed beside series computed according to the law of the expanded binomial, the same which is applied in the theory of probabilities to such calculations as that of the proportionate distribution of less probable events on each side of a most probable maximum term, the distribution of errors of observation of a single object, and of accidental variations in general. It is the closeness of approximation between the observed and calculated series of variations, computed not only as to the dimensions, but the actions of man, which gives to M. Quetelet's theory its remarkable definiteness and precision.

The diagram of statures here figured, which may be looked upon as representing a nation measured in one particular way, at once impresses on the mind a conception of a race-type materially differing from the vague notions hitherto current. It is seen that individual men of different statures are required to constitute a nation, but they are required in less and less proportion as they depart in excess or defect from the central type. The nation is not even complete without its dwarfs and giants. In fact, if all the monstrously short and tall men of a particular country were put out of sight, and the census of the population taken according to stature, the national formula thence deduced would enable a statistician to reckon with considerable accuracy how many dwarfs and giants of each size had been removed.

M. Quetelet's investigations further prove, or tend to prove, that similar laws of variation from the central type govern the distribution of individuals classed according to other bodily dimensions, and also according to physical qualities such as weight and strength, it being borne in mind that the particular expressions with their descriptive curves differ for the various qualities or faculties of man, being also in some cases much less symmetrical than in others. An absolute coincidence of the series of observed facts with the numerical law chosen to express them would be too much to expect; it is a great deal to obtain even a rough coincidence. For instance, when the strength of a number of men is estimated by a dynamometer, the maximum number showed 140 to 150 degrees on the scale, the number of weaker and stronger men being both fewer from this point, groups following approximately the proportions of the coefficients of a binomial of the 6th order; the numbers are reduced as follows from the table (Anthropom. p. 365):—

Renal force, degrees . . .	90	100-110	120-130	140-150	160-170
No. of men in 64 . . .	1	8	14	20	15
Binom. coeff.	1	6	15	20	15
Renal force, degrees . . .	180-190	200			
No. of men in 64 . . .	6	1			
Binom. coeff.	6	1			

In the various numerical examples here given, the element of age is not introduced, the ages of the individuals being calculated or taken as uniform. The problem of variation of numerical distribution of a population at different ages is treated by M. Quetelet in a comparatively simple case, that of the stature-curve. Here a curve approximating to a parabola is laid down, the ages of man from birth onward being measured along its axis; each double ordinate of this curve forms the base on which a binomial curve is erected perpendicularly, the vertices of these curves forming a curve of mean stature, of the nature of a curve of mortality (Anthropom. p. 264). How far M. Quetelet may succeed in his contemplated purpose of carrying his method from the physical into the intellectual and moral nature of man, it is premature to judge.

Without entering into the more intricate and difficult problems opened by this theory of central types, it is evident that the bearing of its main conception on the problems of anthropology and biology in general is highly important. Some able anthropologists have accepted the theory of the mean or central standard as a basis for the comparison of races, but this line of research is still in its infancy. In M. Quetelet's last volume a principle is worked out which serves as a bridge between the old and new methods. His experience is that in a well-marked population no extraordinary number of observations is required for the determination of the mean man. In former ages, one result of the national type being so preponderant in number and so easily recognisable was that the bodily measurements of any man of ordinary stature and proportions could be trusted to give, with reasonable accuracy, the standard measures of the nation, such as the foot, cubit, fathom, &c. In the same manner M. Quetelet finds a small number of selected individuals sufficient for ascertaining the standard national proportions of the human body, male and female, from year to year of growth; his tables, founded for the most part on Belgian models, are given in an appendix. This method is applicable to the purposes of general anthropology. Thus a traveller, studying some African or American race, has to select by mere inspection a moderate number of typical men and women, by comparison of whose accurately ad-measured proportions he may approximate very closely to a central race-type.* It is not necessary to dwell on the obvious difficulties of connecting the standard types of mixed nations with the races composing them. The stature-curve of England differs visibly in proportions from that of Italy, the measurements of Scotch and American soldiers show very different mean and extreme terms, and the problems of race underlying these differences are of a most complex character, the more so when the consideration is introduced of the race-type varying within itself from century to century. M. Quetelet is naturally apt, when expressing his views in an exordium or a peroration, to draw a good deal on the anticipated future results of his admirable method; but in judging of the value of his doctrine of central types, the best criterion is his actual success in reducing the observed facts of nature to numerical

* Thus General Lefroy's measurements of thirty-three Chipewyan Indians ("Journal of the Ethnological Society," vol. ii. p. 44, 1870) are sufficient to determine the stature of the mean man as about 5 ft. 7 in., the number of individuals in this maximum group being 8. It is even possible to guess from this small number of measurements the numerical law of variation in the tribe, the series of groups from 5 ft. 3 in. to 5 ft. 11 in. being as follows:—1, 2¹, 2¹, 6, 8, 4¹, 4¹, 3, 1.

calculation. The future must show how far it will be possible to apply to the theory of species the definition of central specific forms, from which varieties calculably diminish in numbers as they depart in type.

E. B. TYLOR

OUR BOOK SHELF

Magnetism. By Sir W. Snow Harris and H. M. Noad. (London: Lockwood and Co.)

THIS is a good book, and we are glad to see the subject of magnetism fully treated in a popularly written text-book. It is a second edition of Sir William Snow Harris's rudimentary treatise, with considerable and important additions by the editor. The part of chief importance which is added is Chapter viii., which deals with the more recent progress of terrestrial magnetism. This chapter consists of thirty pages, and the author has managed to condense into that space a wonderfully large amount of interesting, useful, and accurate information on the subject. In so short a space we must be content with results rather than with particulars, but the matter contained in this chapter, in point of importance, accuracy, and exhaustiveness, places the present treatise, as far as terrestrial magnetism is concerned, much before any similar book with which we are acquainted. The correction of the compass in iron ships is entered into in the last chapter. The telegraph is scarcely touched upon, but this perhaps rather belongs to a treatise on electricity. We have a chapter on theories of terrestrial magnetism. The theory of Gauss should never be classed, as it is here, and indeed as it is generally classed, along with theories like those of Halley or Hanstein, or with such things as electro-magnetic theories and the like. The word "theory" in these cases means quite a different thing from what it means when applied to Gauss's investigations. Hanstein and the like all make some physical hypothesis, which may or may not be the case; but Gauss makes no such assumption at all, except in so far as he supposes that the needle at all parts of the earth's surface is affected by forces due to the same origin, and varying inversely as the square of the distance, which has been experimentally proved to be the law according to which magnetic forces act. He then shows how the effect on a needle can be expressed in terms of an infinite series which is necessarily mathematically convergent and true, and he then uses an approximation to that series, which approximation is justified fully by experiments similar to those made by the late Prof. Forbes at the top and bottom of the Faulhorn. Gauss's theory, then, is a truly scientific theory, inasmuch as it involves no unjustified physical hypothesis, but is a logical deduction from observed facts and established principles, and in this differs radically from the other theories which are too often classed with it. Dr. Noad has been so successful in Chapter viii. that we cannot help wishing he had introduced a chapter also on this subject.

JAMES STUART

The Amateur's Flower-Garden: a Handy Guide to the Formation and Management of the Flower Garden and the Cultivation of Garden Flowers. By Shirley Hibberd. Illustrated with coloured plates and wood engravings. (London: Groombridge and Son, 1871.)

MR. HIBBERD is a practised writer on gardening subjects, though his books have not much claim to be considered as scientific treatises, but rather as pretty gift-books to lie on the drawing-room table and give to its furniture a quasi-scientific air. That they have their use cannot be doubted, but it is not a very high one. The worst part of this book is the illustrations. From the letter-press may be doubtless culled some useful hints as to the planting and management of a flower-garden,

though we do not think it equal in this respect to some other works, such as those by Mr. Robinson, which are less under the trammels of time-honoured prejudices and superstitions. But many of the illustrations, including some of the woodcuts and nearly all the coloured plates, are simply atrocious. The drawings of a show pelargonium (p. 80), pansy (p. 45), ranunculus (p. 156), carnation (p. 117), and some others, are mere caricatures, and unworthy of a place in any work which bears the least pretensions to a scientific character.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

The Survival of the Fittest

I HAD designed sending a note to you, critical of the abstract of my paper on "The Laws of Organic Development," republished from the *American Naturalist* in one of your recent issues, before I read the remarks of Mr. Spencer in your number of February 1.

If Mr. Spencer will examine the Essay itself (for sale by McCalla and Staveland, 237, Dock Street, Phila., or Naturalists' Book Agency, Salem, Mass.) he will find that I have there exclusively employed his phrase "Survival of the Fittest." The expression "Preservation of the Fittest," not used by Mr. Spencer, was inadvertently introduced in writing the abstract. This was done hurriedly between the sittings of the Amer. Assoc. Adv. Sci. for a reporter of the *New York Tribune*, and was subsequently printed by the *Naturalist* while I was absent on the Plains of Kansas. It therefore contains several obscurities, the result of an attempt to abridge, and a number of typographical blunders. The essay will be found to be free from these.

There being no misrepresentation of Mr. Spencer's views on this point, I notice the second objection he makes. Where, in the sentence regarding the Survival of the Fittest, I say that "this neat expression no doubt covers the case, but it leaves the origin of the fittest entirely untouched," Mr. Spencer regards my language as an "indirect statement that I" (Mr. S.) "have done nothing to explain the origin of the fittest."

It is plain enough that my remark does not apply to Mr. Spencer or to his writings, but exclusively to the doctrine of Natural Selection, and to Mr. Spencer's terse phrase, "which no doubt covers the case," i.e. Natural Selection (not the whole theory of Evolution). I cannot see that this language can be tortured into the interpretation Mr. Spencer places upon it, but Mr. Spencer's language decidedly implies that my statement is literally correct.

I am, however, well aware that Mr. Spencer has done more than any living man to explain the "Origin of the Fittest," and on this account in particular his name does not appear in my criticism. Another reason for its omission is that I have taken the liberty not to read his work, "The Principles of Biology," because I have suspected, from my reading of other works of this philosopher, that it is in advance of other treatises on the subject. I postponed it until, by investigation "in the shop," I should have attained to some definite views based on reasoning uninfluenced by the opinions of others, hoping to use "The Principles of Biology" thereafter in such a way as its merits and justice to its author should require.

EDWARD D. COPE

Philadelphia, Feb. 20

Ethnology and Spiritualism

THERE is only one point in Mr. Tylor's communication (*NATURE*, Feb. 29, p. 343) on which it seems desirable that I should say a few words, in order that I may not be supposed to assent to what I conceive to be a most erroneous view. Mr. Tylor suggests that the phenomena that occur in the presence of what are called mediums, are or may be of the same nature as the subjective impressions of persons under the influence of a powerful mesmeriser. Five and twenty years ago I was myself

* Under the title, "The Method of Creation of Organic Types."

a practised mesmeriser, and was able to produce on my own patients almost the whole range of phenomena which are exhibited in public as illustrative of "mesmerism" or "electrobiology." I carried on numerous experiments in private, and paid especial attention to the conditions under which the phenomena occur. During the last seven years I have had repeated opportunities of examining the phenomena that occur in the presence of so-called "mediums," often under such favourable conditions as to render trick or imposture simply impossible. I believe, therefore, I may lay claim to some qualifications for comparing the mesmeric with the mediumistic phenomena with especial reference to Mr. Tylor's suggestion, and I find that there are two great characteristics that broadly distinguish the one from the other.

1. The mesmerised patient never has doubts of the reality of what he sees or hears. He is like a dreamer to whom the most incongruous circumstances suggest no idea of incongruity, and he never inquires if what he thinks he perceives harmonises with his actual surroundings. He has, moreover, lost his memory of what and where he was a few moments before, and can give no account, for instance, of how he has managed to get out of a lecture-room in London to which he came as a spectator half an hour before, on to an Atlantic steamer in a hurricane, or into the recesses of a tropical forest.

The assistants at the *séances* of Mr. Home or Mrs. Guppy are not in this state, as I can personally testify, and as the almost invariable suspicion with which the phenomena are at first regarded clearly demonstrates. They do not lose memory of the immediately preceding events; they criticise, they examine, they take notes, they suggest tests—none of which the mesmerised patient ever does.

2. The mesmeriser has the power of acting on "certain sensitive individuals" (not on "assemblies" of people, as Mr. Tylor suggests), and all experience shows that those who are thus sensitive to any one operator are but a small proportion of the population, and these almost always require previous manipulation with passive submission to the operator. The number who can be acted upon without such previous manipulation is very small, probably much less than one per cent. But there is no such limitation to the number of persons who simultaneously see the mediumistic phenomena. The visitors to Mr. Home or Mrs. Guppy all see whatever occurs of a physical nature, as the records of hundreds of sittings demonstrate.

The two classes of phenomena, therefore, differ fundamentally; and it is a most convincing proof of Mr. Tylor's very slender acquaintance with either of them, that he should even suggest their identity. The real connection between them is quite in an opposite direction. It is the mediums, not the assistants, who are "sensitives." They are almost always subject to the mesmeric influence, and they often exhibit all the characteristic phenomena of coma, trance, rigidity, and abnormal sense-power. Conversely, the most sensitive mesmeric patients are almost invariably mediums. The idea that it is necessary for me to inform "spiritualists" that I believe in the power of mesmerisers to make their patient believe what they please, and that this "information" might "bring about investigations leading to valuable results," is really amusing, considering that such investigations took place twenty years ago, and led to this important result—that almost all the most experienced mesmerists (Prof. Gregory, Dr. Elliotson, Dr. Reichenbach, and many others) became spiritualists! If Mr. Tylor's suggestion had any value, these are the very men who ought to have demonstrated the subjective nature of mediumistic phenomena; but, on the contrary, as soon as they had the opportunity of personally investigating them, they all of them saw and admitted their objective reality.

ALFRED R. WALLACE

Development of Barometric Depressions

If I have misrepresented Mr. Ley's views, the misrepresentation was certainly unintentional; but after fairly considering his letter in NATURE of February 29, I am unable to see that I have misrepresented his views, so far as they are exposed in his "Laws of the Winds prevailing in Western Europe." Part II., of course, I ignored. It is not yet published; for aught I know, is not yet written; and as I have not the pleasure of a personal acquaintance with Mr. Ley, it is difficult to understand how I could be expected to express any opinion on a book which is still in the womb of the future. But as to the present work,

Part I., which I read and reviewed, it is mainly occupied with instances, ingeniously worked out, in illustration of the rule which he distinctly enunciates, that revolving storms are due to the depression of the barometer caused by a heavy rain over a large area. Perhaps, in the same way, Part II. is to be mainly occupied by an examination and discussion of the still more numerous instances in which revolving storms have not followed heavy rain over a large area; and if so, I shall be glad in due time to give it my best attention. But for the present, having before me merely the author's existing work, I repeat what I have, in effect, already said, that the occasional or even frequent sequence of rain and storm does not establish between the two a relationship of cause and effect.

A very casual examination of our own registers, and those of Western Europe generally, would show that instances of rainfall quite as great as any that Mr. Ley adduces, happen very frequently without any storm following; and clearly if Mr. Ley's rule is sound, it must apply to all instances which cannot be claimed as exceptions, and that not only in our own latitudes, but in other parts of the world, and especially in those parts where the rainfall is excessive. It was certainly not "necessary" to travel to Khasia for instances of the failure of this rule; but its failure was exhibited in the most full and clear manner by a reference to that extraordinary rainfall.

Mr. Ley speaks of some "fact" relative to the Himalayas which "may be denied." I do not quite understand what fact he means. The facts I have spoken of are the "heavy and long continued precipitation," and a very great depression of the barometer." If it is either of these that he wishes to deny, I can only say that his doing so confirms my former statement that he has confined his investigations too exclusively to Western Europe. But when I spoke of the one as causing the other, it was not as stating a fact, but as suggesting a probability; whilst whether there is or is not "a region in which Ballot's rules are contravened" I am unable to say; if there is I have not discovered it, and I don't know where it is, but it is not near the Himalayas, where, so far as we know, the circuit of the wind is quite in accordance with Buys Ballot's Law, though on a scale of extreme magnitude—of such magnitude indeed that our observations do not extend to the end of it. It is curious that an author who, like Mr. Ley, writes sensibly within his professed boundaries, should have limited his studies so closely as he appears to have done; but as the remark to which I have just referred shows pretty conclusively that he has not examined into the range of the barometer in India, so the remark which he makes about the advance of cyclones "in the West Indies, *e.g.*," shows that he is strangely in the dark as to the variations of temperature in the tropical Atlantic.

The columns of NATURE are not the place to discuss at length such well-worn subjects as either Buys Ballot's law or the influence of the earth's rotation, and certainly whether the earth's rotation does or does not produce the effect attributed to it, was quite beyond the scope of my former allusion to it; but I said and repeat that its influence is not "obvious," that an argument based on it is not a "truism," and that to apply these words to a point that is at any rate doubtful is both objectionable and improper.

J. K. L.

Solar Intensity

I HAVE read with interest the criticism in your last number of Padre Secchi's Solar Intensity Apparatus. With reference to the single point of the discordant results obtained by thermometers with bulbs of different size, I would observe that I encountered a similar difficulty some years ago in investigating the adaptability of the instrument invented by Herschel, commonly called the "black bulb *in vacuo*," to regular comparable meteorological observations. I found that the large bulbs always gave a higher reading than the small bulbs. I supposed this to proceed from the colder stem depriving the blackened bulb of its heat, the larger bulb, of course, losing less than the smaller, and I overcame the difficulty entirely by having about an inch of the stem as well as the bulb coated with lamp-black. I am not sure, however, that this would answer so well in a non-exhausted chamber. Probably a small bulb will always be cooled by convection more rapidly than a large one.

In the excess of the temperature indicated by the improved instruments I have referred to over the temperature of the air, at the same height—usually 4 ft.—above the soil (which is also very

nearly the temperature of the outer glass in which the blackened thermometer is enclosed), we have not indeed an absolute measure of solar intensity; for all measures of that must, it would seem, depend on the substance exposed and the conditions as to cooling, &c., under which the exposure takes place, but a sensitive test by which slight variations in its amount can be determined, and the amount at different places and different times compared.

F. W. STOW

The Aurora of February 4

THE following is an account of the aurora of February 4 as seen by a gentleman living in Russia, at Anspatt, in the province of Vitebsk. After stating that the barometer had risen very high (30.2), he says:—"To-night, as I drove home from Reugarten, there was the most beautiful aurora borealis I ever saw." It began in the north-west, and gradually rose higher and higher, till at last it reached the horizon a little north of east, and such a broad band, or rather succession of bands, that it covered half the heavens. It was a bright rose colour, and its light and colour were reflected by the snow, so that the whole earth was rosy; though it was between nine and ten o'clock, and there was no moon, it was nearly as light as day. It is still in full force as I am writing, and I can see it from my window, but it constantly changes its form and colour." I think the latitude of the place is 56 or 57.

J. M. H.

Aurora Island

NATURE for May 25 (which has only just reached this part of the world) contains a note respecting the reported disappearance of Aurora Island in the New Hebrides. In that note the small unpraised coral island of that name north-east of Tahiti is confounded with Aurora—a high volcanic island—more than 40° to the west of the former. It is scarcely to be wondered at that the mistake should be made when the name of the island is alone given; but when "Aurora Island, one of the New Hebrides group," is spoken of as being to the "north-eastward" of the well-known island of Tahiti one feels surprised at the misconception.

Has it yet been clearly defined to which Aurora the report refers, and is it not more probable that the captain's chronometer was out, or that his reckoning was incorrect, than that either island has really been submerged? A few months ago Dr. George Bennett, F.L.S., of Sydney, New South Wales, showed me a sketch which he made of Aurora in the New Hebrides some years ago. From that the island appears very mountainous, and the map of Melanesia, in Petermann's *Geographische Mittheilungen* (1870), makes it about twenty miles long and 2,000 ft. high.

S. J. WHITMEE

Samoa, South Pacific, Nov. 4, 1871

P.S.—The following notes of earthquakes in the Samoa group may be of interest to some of your readers:—

May 14, 1871.—2.5 P.M. First a vertical, followed by a horizontal, shock.

July 1, " —9.30 A.M. Slight horizontal shock.

" 16, " —12.10 P.M. Vertical shock.

Aug. 3, " —12.15 P.M. Slight horizontal shock, accompanied by a loud rumbling noise.

Sept. 23, " —6.45 A.M. A slight horizontal shock.

I was absent from Samoa from September 1870 to April 1871. During that time there were eight shocks of earthquake in the group; but the dates and other particulars were not noted. One is reported as having been the most severe shock known here. Earthquakes have been more frequent in Samoa for the past year or two than formerly.

FOUL AIR IN MINES AND HOW TO LIVE IN IT

I.

I BEG to forward you for publication in NATURE an account of some very interesting experiments recently made at Chatham, on the employment of a respirator in military mining. They were conducted in a

thoroughly practical manner by Mr. J. Edward Gibbs, a highly intelligent young officer of Engineers, who, I may add, has given the respirator a very convenient form, and, I trust, will continue the work he has so well begun.

It is to be borne in mind that the cotton wool employed in the respirator is not to be steeped in glycerine, but moistened with this substance; the wool ought to be well teased until all its fibres are wetted, at they must not form a clot.

JOHN TYNDALL

"When on duty at the Defensive Mines one day during the mining operations of July and August 1871, three men were brought out in a fainting state, caused by a rush of foul air in untamping. Thinking some means might be devised for preventing such accidents, and the consequent loss of time and panic, I consulted with Captain Malcolm, R.E., who proposed Prof. Tyndall's firemen's respirator for consideration. Colonel Lennox sent me to the maker to inquire, and I returned with one.

"With the assistance of Quartermaster-Sergeant Ingram of the Chemical Laboratory, and several books of reference, I have collected the following notes:—

"After exploding a charge of gunpowder at a gallery-head, it becomes dangerous to untamp, because of the poisonous gases produced by the combustion of the powder. These gases are CO₂, N, CO, HS, C₂H₄, and H. The only gases that are present in sufficient quantities to harm are CO₂ and CO. CO₂ to the amount of $\frac{1}{10}$ ('005) of the bulk of the air at the gallery-head would render it unfit to sustain life. CO to the amount of $\frac{1}{10}$ ('01) would do the same. 100 lbs. of powder evolve 22559.38 cubic in. of gas at 60° F. and 30" B., of which 9429.7896 are CO₂, and 2249.848 are CO.

"Miners working in the presence of the foul air from the explosion suffer in two ways. If affected suddenly, they feel a burning at the nape of the neck, and their limbs tremble, they turn giddy and faint. This is to be attributed chiefly to the CO. The miners are also affected in a slower manner by the CO₂. They feel their breathing becoming difficult, as if there were a weight on their chest, with a tight feeling in the head; if not brought into the fresh air they are in time overcome and faint. This also brings on headache, on coming into fresh air.

"Any method of getting rid of the foul gases by chemical means must interfere greatly with the progress of the work. In any case there would be considerable difficulty in destroying the CO, as it has neither acid nor basic properties. A good system of ventilation through hose would clear the galleries of the foul air, but would not overcome the difficulty of untamping, because at any moment of the process there may be a rush of foul gas, which would take effect on the men at work, before the ventilation could carry it away.

"A good respirator worn by each of the men employed at untamping might overcome this difficulty. Prof. Tyndall's respirator for firemen is constructed with a view to enable the men to inhale pure air when at work in a burning house, by separating the smoke and noxious vapours. It consists of two parts; (1) the mouth-piece; (2) the body of the respirator.

"The mouth-piece is an invention of a Mr. Carrick, hotel-keeper at Glasgow, who had patented it.* It has two valves, *z* and *e*. (See NATURE, June 15, 1871.) The air inhaled comes from below, up through the body of the respirator and through *z*. The exhaled breath closes *z*, and escapes through *e*, thus keeping the contents of the body of the respirator cool. There is an aperture *o*, which fits closely round the lips, and to prevent respiration through the nose, there is a nose-pad fixed on top of the mouth-piece. A wire-gauze partition separates the mouth-piece from the contents of the body of the respirator.

* This is not the mouth-piece now adopted.—J.T.

"The body of the respirator is about 4in. or 5in. long, and contains at the top a layer of cotton wool, moistened with glycerine to prevent any solid particles escaping into the mouth from lower layers, and also to stop those very minute particles of the smoke that may not have been arrested below. Next comes a layer of dry cotton wool, then a layer of charcoal fragments, another layer of dry cotton wool, and then some fragments of slaked lime. Below this comes some more cotton wool, and then the wire-gauze cover or cap at the bottom.*

"For smoke the layer of lime is not necessary, but in the mines it would be of the greatest use, because it has a great attraction for CO_2 . The layer of charcoal would absorb the CO and the HS in the air, and the mixture inhaled would be perfectly innocuous. The disadvantages of this respirator in its present form for mining purposes are—that it is too long, and an effort is required in breathing through the small valves.† Mr. Ladd, of Beak Street, Regent Street, the maker of these respirators, has made some improvements in the mouth-piece, which may overcome some of the inconveniences of the old pattern.

"I received permission to use the R.E. workshops for experimenting on the shape best suited for use in the mines. Tyndall's respirator has been severely tested in dense and pungent smoke from pinewood, and it succeeded to the perfect satisfaction of Captain Shaw, Chief Officer of the London Fire Brigade. Firemen are to wear it attached to hide helmets, but for the mines any arrangement which will support the respirator and keep it close to the mouth during work, without being hot or uncomfortable, will suffice.

"*Experiments made with the Respirator.*—On Saturday, August 19, 1871, a trial of the respirator was made in the Chemical Laboratory, S.M.E., in the presence of Colonel Lennox, Dr. Fox, and others. I was shut up in an air-tight cupboard, with the respirator on. By my side were jars containing CO and CO_2 in a proportion of 500 each of the cubic content of the cupboard (141,698·4 cubic in.), not allowing for the space occupied by my own body and the stool on which I sat. The respirator contained animal charcoal and lumps of slaked lime mixed together, thus dispensing with one layer of cotton wool. After emptying all the jars, I remained for ten minutes in the full mixture (fifteen minutes in all) without the slightest discomfort except from the awkward shape of the respirator. I was then called out.

"On Monday, the 21st, another trial was made in the presence of Dr. Fox and Lieuts. Abney and Galwey. This time a rabbit and three birds were placed in the cupboard with me. The respirator contained, in addition to the charcoal and slaked lime, a small quantity of sulphate of soda. The only cotton wool used was a small layer soaked‡ in glycerine at the top, and a thin layer of dry wool at the bottom. The sulphate of soda was introduced according to Prof. Graham's advice, in order to give an atom of O to the CO to form CO_2 , becoming itself sulphite of soda. The content of the cupboard is 141,698·4 cubic in.: from this would have to be deducted the space taken up by my body, say $3\frac{1}{2}$ cubic ft. (Dr. Parke's Hygiene), or, roughly, 6,000 cubic in., leaving 135,698 cubic in. 1,890 cubic in. of CO_2 in jars were introduced from a pressure bag, making altogether:—

1,890 cubic in. of CO_2
1,921 cubic in. of CO,

or 3,811 cubic in. of poisonous gases in addition to my exhaled breath, or about 3 per cent. of the capacity of the cupboard. In order to perfect the mixture of the gases, I waved a towel about constantly, and after the end of

the trial, a taper being extinguished at the top of the cupboard showed that the CO_2 had been stirred up to the top. The rabbit and two birds died at the same time, about twenty-three minutes after the cupboard was closed, while the CO from the pressure bag was being introduced. I stayed in the cupboard thirty minutes (five minutes after the mixture was completed and seven minutes after the death of the animals). When I came out I felt a pressure on my ears, as when descending too rapidly in diving. Dr. Fox said that this was produced by my blood, my heart then beating at a high rate.

"This is satisfactory, as showing that the gases had not affected me, but only the exertion of breathing through the respirator, for thirty minutes, combined with the heat of the close atmosphere in which I was.

"To prove that the gases did not affect me, I quote some extracts from Dr. Park's 'Hygiene':—"Dr. Angus Smith says the breathing of CO_2 to the extent of 1·5 to 2 per cent. produces slowness of heart action, while the respirations become quickened if not gasping; this is perceptible with as little as 1 per cent. Less than $\frac{1}{2}$ per cent. of CO has produced poisonous symptoms, and more than 1 per cent. is rapidly fatal to animals. CO in excess produces loss of consciousness, slowness of heart action, and finally paralysis of the heart.

"The slowness of diffusion of the two gases was remarkably shown by the effect on the third bird. The cage which held it was suspended at the top of the cupboard. The bottom, back, and top were of wood, the other sides were of wood for about $1\frac{1}{2}$ in. and then of wire. The bird, which was at first on a perch, was very soon affected by the impure air, and fell to the bottom of the cage. Here the wooden bottom and sides evidently supported a layer of pure air, for although the bird had lost consciousness, and indeed was considered to be dead, yet after being brought out into fresh air, it was revived by ammonia, and after an hour or so fluttered away. The other animals, that were not so protected, died before all the gases had been introduced.

"On examining the sulphate of soda, very little was found to have been changed into the sulphite; it would, therefore, seem that a constant change occurred, the sulphate giving up oxygen to the CO, becoming sulphite, and then the sulphite taking oxygen from the air to form the sulphate. Whether the good effect of the first change compensates for the loss of free oxygen in the second change is a question for the opinion of a chemist; however, Prof. Graham's recommendation is of great weight.

"All that were present agreed that the trial was perfectly satisfactory, and I think this is a fair conclusion. For the object in view throughout has been to devise some plan by which a man may work for some time in a foul mine, and may be secure from the effects of a rush of foul gas caused in untamping, &c.

"Defensive mines, though small, poison the ground more effectively than overcharged mines, which allow most of the gas to escape. I have before shown the total amount of CO and CO_2 evolved by the explosion of 100 lbs. of powder, which, according to our late operations, seems to be an average charge. It is probable that a large proportion of these gases would escape into the air, and that the rest would be diffused equally all round the charge. Therefore only a small amount is likely to be encountered at any one point. Hence it would seem that the respirator, which has succeeded with very powerful mixtures of poisoned air, would be quite enough to guard the miners from any of the gases from explosions.

"It only remains now to hit upon a convenient shape which will not render the breathing laborious. If we succeed in this, it is likely that the respirator would be of use also in civil work, such as exploring mines in search of bodies after a colliery accident."‡

J. E. G.

* This order may be varied in different ways without prejudice to the respirator.
† These objections have been in great part met by the recent forms of the respirator.

‡ See remark in the introduction above.

* This is one of the purposes contemplated by myself, but the suggestion of Mr. Gibbs is independent and original.—J. T.

THE STRUCTURE OF THE CORONA

AMONG the parties organised to observe the Total Eclipse of 1869, Aug. 7, that sent from the Cincinnati Observatory was probably favoured above all others in the advantage of having a comparatively elevated station and an exquisite atmosphere. The publication of the work done by this party has been delayed by the fact that for a year subsequent to the eclipse I was wholly absorbed in the labour attending the maintenance of the "Weather Bulletin of the Cincinnati Observatory," and my subsequent occupations in the present office have entirely prevented me thus far from even attempting the reduction of our observations: the original note-books are at present packed away with the library of the Observatory, awaiting the removal and rebuilding of that institution.

My own attention was expressly given to the structure of the corona and coronal streamers, for which purpose I used the full aperture of an exquisite six-inch objective (one that had received a prize at the Paris Exposition Universelle), and which was loaned to the Eclipse Expedition by Mr. T. G. Taylor, of Philadelphia.

A short notice of the principal features noted by myself was sent at once to the editor of the *Astronomische*

Nachrichten, but has not yet been published, and I therefore take the liberty of restating through your wide-spread journal the simple phenomena that I then saw.

Our station was at Sioux Falls City (formerly Fort Dakotah), in the south-eastern corner of Dakotah Territory, latitude 44° , longitude 97° , elevation about 1,500 feet above sea-level, in the midst of an extended plateau. Rain and cloud had continued up to a few hours previous to the critical moment, but the atmosphere during the eclipse was of surpassing steadiness and clearness.

The altitude of the sun at time of totality was about 40° , the local time 3.30 P.M., the duration of totality 4 minutes. No sooner had totality begun than, after sketching in most of the prominences as points of reference, I viewed the corona without darkening glasses, and with a magnifying power of probably 120 diameters. The whole interval of totality was, unfortunately, not at my disposal, owing partly to the very rough and faulty stand supporting the telescope (everything had to be transported 100 miles by mules into a wilderness), and partly to an interruption by one of the members of the party; but there seemed to me to be no doubt of the facts as recorded, nor was I conscious

of the least undue emotion that might have interfered with my reliability as a witness, although it was the first total eclipse that I have had the pleasure of observing.

As seen through my inverting telescope, the structure of the large protuberance on the right hand lower limb was well made out. The neighbourhood of the sun was examined to a distance of its own diameter (a radius of possibly one degree from the sun's centre), but no trace of the coronal rays as they were seen by others of my party. The evidence as to the existence, shape, and positions of these streamers, as given by my six assistants, was conclusive as to their actual appearance, with the usual variations as to details.

That they were not detected by the six-inch glass was probably due to their diffused light and the small field of view. On the apparent upper and left hand limb of the sun, the six-inch glass showed the long series of red prominences depicted in the photographs published by the Naval Observatory. Above the greater portion of the arc of the sun's limb thus covered, and extending somewhat farther to the right, appeared to rise up three and possibly more conical masses of pearly light.

These were distinctly contrasted against the light diffused as the background of the field of view, and there was every evidence that they had an identical structure and cause. The outline of each of the pearly mountains was that of a rounded cone, as shown in the drawing—exactly resembling the kilns used in some branches of pottery and other manufactures. The apices of the cones were blunted or truncated, and not well defined; the outlines of the sides of the cones were quite sharp down to within a few minutes of the sun's limb, when all three appeared to begin to lose their distinctive characteristics.

The height of the apices above the limb varied between one-half and two-thirds of the solar radius; the diameters of the bases of the cones were probably included between seven and three minutes. Each apex was of a slightly dusky shade compared with the body of the cone.

The most interesting feature was an unmistakable striation upon the surface of each cone; the striæ apparently twisting spirally around up to the apex opposite to the movement of the hands of a watch, as represented in the accompanying drawing.

I noticed no colouration of these striæ other than their darker hue. The details of this striking and new phenomenon interested me so much that I naturally enough lost the observation of the third contact. The pearly cones were on that limb of the sun from which the moon was moving, and the details were every moment becoming more distinct, when the growing height of the bank of red protuberances was followed by the too speedy apparition of the glowing sun beneath.

Chagrin at the loss or imperfect observation of the third contact caused me to forget to note whether the three cones continued in view for any number of seconds thereafter. From the time of first recognising the pearly cones, until their disappearance, probably thirty seconds elapsed (I am writing without my note-book or other aid to memory), and I did not note any change in the appearance of the striæ.

The middle one of these cones caught my eye more especially, and the impression was that the other two, especially that on the right, was some distance behind it, or possibly obscured by a cloud of haze in the solar atmosphere. At the time it seemed to me that I saw in the central cone a column of smoke and hot gas ascending high above the area of red flames, then visible on the surface of the sun, and that the other two cones corresponded to other areas of red flames behind. The difference in character and position between these cones and the coronal streamers as observed by the others with the naked eye, and with opera glasses, seemed to argue that the latter were very probably individual subjective phenomena, or that they originated in the earth's atmosphere

whilst the pearly cones existed in the solar atmosphere and constituted a true solar corona.

My long delay in making this communication to the scientific world will be excused, I trust, in view of the imperative demands made upon my time during the two years that have elapsed since the Eclipse of 1869. I shall be deeply interested to learn whether the phenomena seen by myself may not be repeated on some other occasion and be studied by more experienced observers.

I may add that I had hastily provided myself with a Nicol's prism in hopes of making at least some trial of the nature of the coronal light; but the rude apparatus did not work satisfactorily, and I confined myself to details of structure; indeed, in my earnest gaze upon the novel phenomena I quite forgot the polarising apparatus.

Washington, Feb. 6, 1872

EARTH-CURRENTS AND THE AURORA BOREALIS OF FEBRUARY 4, 1872

IT is unfortunate that more accurate observations of the electrical phenomena accompanying auroral displays cannot be made upon the telegraph wires of this country. The truth is, public business cannot be made to suffer for scientific investigation, and at such moments the disturbance of the wires makes it more than ever imperative that delays should not occur. The whole efforts of the staff are directed to maintain the communications intact, hence the observations made on February 4 are not very numerous, though they are sufficiently interesting to deserve record.

At Portsmouth twenty-six observations were made of the direction and strength of the earth-currents on a wire extending from Portsmouth to London, *via* the London and South-Western Railway—a length of 74 miles, giving a resistance of 995 ohms. These were as follows:—

Time.	Direction of	Strength.	Remarks.	Time.	Direction of	Strength.	Remarks.
5.54	P	30°	The observations were made upon an ordinary vertical galvanometer, and 40° was equal to about 20 Daniell's cells.	6.41	P	40°	{No observations made between 6.41 & 7.35.
6.8	"	20		7.35	"	0	
6.11	"	10		7.42	N	41	
6.13	"	30		7.56	"	68	
6.15	"	25		8.6	"	0	{No observations made between 8.30 & 9.0 P.M.
6.17	"	40		8.8	"	0	
6.19	"	30		8.15	N	35	
6.21	N	15		8.22	P	12	
6.23	"	24		8.28	"	0	
6.25	P	20		8.30	"	0	
6.27	"	0		—	—	—	
6.29	—	0		9.0	—	0	
6.31	P	8		9.40	—	0	
6.33	"	13					

P means Positive from London to Portsmouth.

The officer who made these observations writes:—"Strong deflections arising from earth currents were observed on all circuits except the local ones. The duration of the currents changed from north to south at intervals of a few minutes, and varied in strength from 1° to 68°. The strength of the current was proportionate to the length of the wire. Thus Chichester circuit (a short one) was affected less than the Guildford, and the latter less than the London circuits. The working was maintained to London with comparative ease by looping two circuits together at each end." The latter method is that usually adopted to overcome the disturbance due to earth currents, but of course it is only applicable in places where there are two wires or more.

Another officer at the Waterloo Station, London, observed the deflections gradually appear on every needle circuit, of which many concentrate at that station. They commenced about 2 P.M., and from that period to 8 P.M. they had all alike been more or less disturbed. It was noticed that the needles moved over gradually, not by a continuous motion, but by jerks, resembling that of the minute hand of a large clock. This has, however, been proved to be due to the friction of the pivots, and not to any pulsations in the currents.

The currents were always most apparent, and first noticeable on the longest lines, and as the lengths of the circuits terminating at Waterloo are very variable, this gradual appearance was very interesting. Lines running south-west and west appear to have been most affected.

All the wires in the Channel Islands were also very much disturbed. In fact Jersey was broken down to England for three hours, owing to the fact of there only being one cable. The section most affected was that between England and Guernsey. It was also noted that the wires in France were very much influenced.

The records from abroad show that, as in previous cases of storms of this character, the effect has been simultaneous all over the globe. The French Atlantic cable was seriously affected; the strength of the current was at one time equal to 90 Daniell cells. It was at times impossible to read even with condensers in circuit. The American lines were also disturbed in the East, West, and North, but not in the South.

It is much to be regretted that simultaneous observations cannot be made in various parts of the globe, detailing, in comprehensible units of measurement, the direction and strength of these currents, as well as the exact time of their appearance and disappearance. We might then arrive at some knowledge of their cause.

Southampton, Feb. 24

W. H. FREECE

THE DARMSTADT POLYTECHNIC SCHOOL

THE following epitome of the programme of the "Grand Ducal Hessian Polytechnic School of Darmstadt" may interest the readers of NATURE as a further illustration of the facilities offered in Germany for technical training of the highest and most practical kind.

The object of the school is stated to be a thorough scientific, as well as artistic, education, for all technical pursuits, assisted by appropriate practical exercises. The institution affords special facilities for the education of architects, engineers, mechanical and chemical technicists, manufacturers, craftsmen, and agriculturists. The institution is divided into the following sections:—(1) the Lower School; (2) the School of Architecture; (3) of Engineering; (4) of Machinery; (5) of Technical Chemistry; and (6) of Agriculture.

The Lower School aims at giving a general instruction in mathematics, natural science, and design, as a foundation for the special pursuits taken up afterwards. For admission into the school it is necessary that the student shall be sixteen years of age, and have received such an education as would be afforded by the highest class of a "Realschule," or the third course of a "Gymnasium," with the exception of the dead languages. This implies a knowledge of algebra, as far as equations of the second order, an acquaintance with logarithms, with plain geometry, and the elements of solid geometry, practice in German style, a knowledge of the outlines of history, and some practice in linear and free-hand drawing.

Examinations are held in the lower school at the end of each half-year, in the other divisions at the end of each year; a diploma is only given if the student gives satisfactory evidence of having completely mastered one of the branches of technical study in which special instruc-

tion is given. The payments consist of an entrance-fee of 5 fl., and a payment of 50 fl. per annum; and in addition 6 fl. is charged for every day's work of 7 hours in the chemical laboratory; 10 fl. for 2 afternoons of 3 hours in the physical laboratory.

In addition to the subjects required in each special department, lectures or instruction are given in the following subjects, and attendance at some of them is strongly recommended to all students, in order to give a wider culture than would be attained by exclusive attention to his special pursuit:—(1) Exercises in Literature and History; (2) the French and English Languages; (3) the General History of Art; (4) National Economy; (5) Commercial Knowledge; (6) the Principles of Jurisprudence; (7) Physical Geography; (8) Zoology; (9) Systematic Botany; (10) Singing and Gymnastics.

The course in the Lower School extends over two years, in which the following subjects are compulsory:—First year. (1) History and Literature with the German Languages; (2) Higher Algebra; (3) Stereometry and Trigonometry; (4) French; (5) Outline Geometry; (6) Free-hand Drawing. Second year. (1) History and Literature with the German Language; (2) Analytical Plane Geometry; (3) Algebraic Analysis, the Differential and Integral Calculus; (4) Higher Algebra; (5) Experimental Physics; (6) Mechanics; (7) French; (8) Free-hand Drawing; (9) Outline Geometry.

In the special schools for Architecture, Engineering, Mechanics, Technical Chemistry, and Agriculture, the entire course extends over a period of from two to four years. The extent to which the studies are carried will be illustrated by the following abstracts of the curriculum in the Agricultural School, the shortest of the courses:—First year (1) Experimental Physics; (2) Experimental Chemistry; (3) Chemical Exercises; (4) Histology and Morphology; (5) Vegetable Physiology; (6) Systematic Botany (with excursions); (7) Zoology; (8) Mineralogy; (9) The Study of Rocks; (10) Anatomy of Domestic Mammalia; (11) Physiology of Domestic Mammalia; (12) External form of Domestic Mammalia; (13) Agricultural Implements and Machines; (14) National Economy; (15) Mathematics; (16) The Drawing of Plans. Second year—(1) Chemical Exercises; (2) Agricultural Chemistry; (3) Practical Microscopy; (4) Practical Physiology; (5) The Diseases of Plants; (6) General Agriculture; (7) Special Agriculture; (8) General Breeding of Animals; (9) Special Breeding of Animals; (10) The Commerce of Agriculture; (11) The Cultivation of Garden, Orchard, and Vine; (12) Internal Diseases of Domestic Mammalia; (13) External Diseases of Domestic Mammalia; (14) Technology (Heating and Lighting); (15) Agricultural Book-keeping; (16) Irrigation, Tilling, &c.; (17) History and Literature of Agriculture; (18) Practical Geometry.

To assist in the studies of the pupils there are chemical and physical laboratories, an experimental farm, mineralogical, zoological, and botanical collections, models of machinery, designs, libraries, excursions into the country, &c. Under special circumstances students can be admitted as "Hospitanten" to certain only of the studies, without going through the entire course; but care is taken that this does not interfere with the regular studies of the other students.

LAKE VILLAGES IN SWITZERLAND

IT is satisfactory to find that the correspondents of some of the daily journals are now in the habit of giving scientific information to their readers. The following is taken from the *Standard*:—

"An interesting archaeological discovery has recently been made on the shores of the Lake of Bienné. The Swiss Government has been for a long time endeavouring to drain a considerable tract of land between the two lakes of Morat and Bienné, but in order to do this

effectually it has been found necessary to lower the level of the latter by cutting a canal from it to the lake of Neuchâtel. At the beginning of the present year the sluices were opened, and the waters of the Lake of Bienné allowed to flow into that of Neuchâtel. Up to the present time the level of the Bieller See has fallen upwards of three feet, and this fall has brought to light a number of stakes driven firmly into the bed of the lake. This fact becoming known, a number of Swiss archaeologists visited the spot, and it was decided to remove the soil round these stakes to see whether any remains of a Lacustrine village, which they suspected had been raised upon them, could be traced. At a distance of between five and six feet from the present bed of the lake the workmen came upon a large number of objects of various kinds, which have been collected and are at present under the custody of Dr. Gross, of Locross. Among them are pieces of cord made from hemp, vases, stags' horns, stone hatchets, and utensils used apparently for cooking. The most precious specimen is, however, a hatchet made of *néphrite* (the name given to a peculiarly hard kind of stone from which the Lacustrines formed their cutting instruments). This hatchet is sixteen centimetres long by seven broad, and is by far the largest yet discovered in any part of Switzerland, no other collection having any measuring more than eight centimetres in length. A quantity of the bones found at the same time have been sent to Dr. Uhlmann, of Münchenbuchsee, for examination by him, and he finds that they belong to the following animals, viz.:—stag, horse, ox, wild boar, pig, goat, beaver, dog, mouse, &c., together with a number of human bones. If the level of the lake continues to sink, it is hoped that further discoveries will be made, and the scientific world here is waiting the result of the engineering operations with keen interest."

NOTES

WE have great pleasure in announcing that Prof. Andrew C. Ramsay, F.R.S., has been appointed Director-General of the Geological Survey in the room of the late Sir Roderick I. Murchison.

At the moment of going to press we have received the announcement of the death of Prof. Goldstickler, the eminent Sanscrit scholar. He died on Wednesday morning.

MR. G. B. AIRY, the Astronomer Royal, and Prof. Agassiz, were elected foreign associates of the *Académie des Sciences* at Paris in the room of the late Sir J. Herschel and Sir R. I. Murchison at the meeting on the 26th ult.

DR. MAXWELL SIMPSON, F.R.S., has been elected as successor to the late Dr. Blyth in the chair of Chemistry, Queen's College, Cork. Dr. Simpson is well known to men of science at home and abroad as an accomplished chemist, and one who has been especially distinguished for his original researches.

THE Crystal Palace Company's School of Art, Science, and Literature is about to take an important step, having for its object the emphasising of the science branch of the school, in order that eventually the south of London may be provided with an institution which, in a measure, may represent the Royal and London Institutions which already exist in the west and centre. The step consists in adding to the courses of lectures on scientific subjects already given special courses to be given from time to time by scientific men of eminence, similar to the courses given in the Institutions before referred to; and it is hoped that the same lectures and the same standard of excellence and illustration may be secured. As the lecture theatre of the school has been burnt down, the lectures, pending its rebuilding, are to be given in the theatre in the Crystal Palace; but it need scarcely be stated that these lectures have no connection with the Crystal Palace, except so far as the School of Art, Science, and Literature is connected with it, and that they will be given at a time when the

Palace is closed to the general public. Mr. Norman Lockyer has consented to give the first course of lectures. This step taken by the Committee is in every way to be commended, and we look with confidence to the success of these lectures as paving the way for others in various parts of the country, which may eventually do much towards popularising Science among the masses.

PROF. P. MARTIN DUNCAN, F.R.S., is now delivering the course of Lectures on Biology to the class for the Higher Education of Women at South Kensington, in the place of Prof. Huxley, who is still in Egypt for the complete restoration of his health.

MR. W. MARSHALL WATTS, D.Sc., of the London University, has been appointed to an assistant mastership in Giggleswick Grammar School, Yorkshire. The governors have settled that chemistry, including practical work in a laboratory, and physics, shall hereafter be taught in the school, and the teaching of these branches of science has been entrusted to Dr. Watts. Until recently Dr. Watts has had the main charge of the teaching of chemistry in the Manchester Grammar School, a school which has been eminently successful in obtaining scholarships in physical science at Oxford. Mr. E. K. Purnell, Scholar and Prizeman at Magdalen College, Cambridge, has also lately been appointed to a classical mastership in Giggleswick School.

THE Council of the St. Andrews Medical Graduates' Association are about to appeal to the many friends of the late Professor of Medicine in the University of St. Andrews, to aid them in an attempt to make a more fitting provision for his widow than Dr. Day's ill-health allowed him to accomplish. We regret to learn that such an appeal is necessary, and heartily wish it success.

THE Haberdashers' Company have recently awarded Mr. Webb, the Senior Wrangler of Cambridge, 50*l.* for three consecutive years; he having been a pupil of the Rev. C. M. Roberts at Monmouth, of which school the Haberdashers' Company are governors. They also propose to grant four exhibitions of 50*l.* to the children or grandchildren or apprentices of Livermen of the Company under certain restrictions, to be tenable for three years. In addition to the above, one exhibition of 50*l.* will be specially granted to a scholar of any school under the Company's management. The sum of 150*l.* will also be appropriated towards assisting the education of children of the Liver of the Company. 100*l.* yearly will also be awarded as a prize to the inventors of anything new in haberdashery.

As the period of the Transit of Venus in 1874 approaches, astronomers both at home and abroad are becoming more and more active in their preparations; and the American committee on this subject, it is understood, has already decided in considerable part upon the stations to be occupied. Of the result of their conclusions we hope to give an account before long to our readers. In Russia the committee, under Prof. Struve, proposes the establishment of a chain of observers, at positions 100 miles apart, along the region comprised between Kamtschatka and the Black Sea. The German committee has decided on recommending the organisation of four stations for heliometric observations of the planet during its transit, one of them in Japan or China, and the others probably at Mauritius, Kerguelen, and Auckland islands; and three of these, with the addition of a fourth station in Persia, between Mascate and Teheran, will be equipped for photographic observations also. The French, before the war, suggested that stations be established at St. Paul Island, New Amsterdam, Yokohama, Tahiti, Noumea, Mascate, and Suez. How far this programme will be carried out under the changed circumstances of that country remains to be seen.

WE have received a letter from a valued correspondent, calling attention to some defects in the arrangements for the study of the Natural Sciences, and especially of Botany, at the University of

Cambridge. The letter we refrain from publishing, in the belief that the good work which is now proceeding at the Universities will be carried out eventually far more completely than it is at present, and that even Botany may ultimately receive the attention that it deserves.

THE Brazilian steamer to New York brings advices of the safe arrival at Pernambuco of the steamer *Hasler*, with Prof. Agassiz and party. They were to leave for Rio Janeiro, in company with the *Ticonderoga*, on Jan. 16. As there are several gentlemen on board who have undertaken to supply information in regard to the movements of the vessel, we shall doubtless before long have full accounts of the progress made up to the date mentioned; although in regard to the subject of deep-sea soundings and supposed discoveries connected therewith we must probably wait, for correct details, for the official report to be made by Count Pourtales direct to the Superintendent of the Coast Survey.

THE "Annual Report of the Secretary of the Interior for the United States on the Operations of the Department for the year ending October 31, 1871," states that the results of Prof. Hayden's expedition, in accordance with his instructions to investigate the geology and natural resources of the little known, but interesting, region about the source of the Yellowstone and Missouri rivers, shows it to have been a complete success, and fully to justify the liberal provision made by Congress for it. A preliminary report of the results was to be presented to Congress at an early date. A great amount of valuable notes and specimens, illustrating the agricultural, mineral, zoological, and botanical wealth of the West, was secured.

WE learn that the Smithsonian Institution has recently succeeded in obtaining two complete skeletons of the remarkable tapir of the highlands of the United States of Colombia, known to naturalists as *Tapirus pinchaque* or *roulini*. Previously only the skull had been obtained by Roulin, by whom it was first made known, and it was one of the rarities of the great anatomical collection at Paris. The Smithsonian Institution had before obtained a number of skulls and a skeleton of the still more remarkable tapir of Panama, which had remained undistinguished from the common species of Panama till within a few years, when first described, under the name of *Elasmognathus bairdii*, by Prof. Gill, from two skulls in the Smithsonian collection. There are no external or dental differences between the tapirs corresponding with the marked differences in the skulls; the external differences being confined to the contour of the forehead, the colour, and the character of the hair. In the mountain tapir, as might be expected in an animal dwelling in such elevated regions, the hair is long and coarse, and is of a black colour, strongly contrasting with that of the common tapir of South America; it is also somewhat smaller than that species, and has the forehead less arched from the occiput. It is confined to the highlands, and is separated, at least so far as is known, by quite a wide band of country from the common species.

THE Report of the officers of the Peabody Academy of Sciences of Salem, lately made to the trustees, presents a satisfactory statement of the progress made during the past year. This establishment received a moderate endowment from George Peabody, of London, and the income is expended in the care of the valuable museum belonging to the Academy. The directors of the establishment are Mr. F. W. Putnam and Dr. Packard. The principal additions to the museum of the Academy during the year have consisted mainly of insects and archaeological specimens, and also a series of the animals inhabiting the Mammoth Cave of Kentucky. All of these, together with the collections previously in the museum, have been properly arranged and classified, and tend to render the museum very attractive. The report urges very strongly the propriety of securing an additional endowment, to enable the Academy to publish in its

memoirs certain valuable scientific manuscripts now in hand, the alternative of being obliged to send them to some other establishment having more means at its disposal being greatly deplored, as they were based upon the collections of the Academy, and should legitimately appear under its auspices.

THE Clifton College Scientific Society has just issued the second part of its Transactions, containing the record of its proceedings from February to July, 1871. The president and secretary state in their Report that the papers read at the Society's meetings have been as numerous as previously, and the attendance of members and visitors has in no degree fallen off; and that, although there is still much to be desired in this respect, yet the number of working members is steadily increasing. The various sections of botany, zoology, entomology, geology, archaeology, chemistry, and physics have, on the whole, done good work, the least satisfactory reports being in the case of zoology, chemistry, and physics. The great event of the half-year has been the long-expected opening of the new Museum and Botanic Garden, both of which institutions are well deserving of support from those outside the school who are able to assist in furnishing them. The Botanic Garden is already one of the very best to be met with anywhere in the provinces. Among the papers read before the society and printed in the Transactions, the following have struck us as especially excellent:—"A Scientific Visit to Cheddar," by the President and J. Stone; "The Church of St. Mary Redcliffe, Bristol," by R. W. Wilson; "The Coalfield of South Wales," by A. Cruttwell; "The Birds of Clifton," by D. Pearce; and an admirable paper on "The Spectrum," by W. A. Smith.

THE last number of the *Bulletin de la Société de Géographie* contains an article by Delesse on the oscillations of the coasts of France.

THE Annual Address, delivered before the Albany Institute, New York, by Orlando Meads, on May 25, 1871, has just reached us. It is chiefly occupied with a sketch of the history of this successful and enterprising institution.

THE *Poona Observer* of February 6 gives the following account of Indian Geological Excursions:—"The Principal of the Poona Civil Engineering College, Mr. T. Cooke, together with the Professor of Chemistry, Mr. S. Cooke, with about twenty students of the first class, proceeded on a geological excursion on January 29, and arrived here on Saturday morning last. After leaving Poona they arrived at Shabad, where they remained for a whole day. The next morning they left Shabad and arrived at Krishna at about ten in the morning, and inspected the Krishna Bridge. After inspecting several works of the G. I. P. R., they started for Poona on the afternoon of Friday. The thanks of the students as well as of the Principals are due to the G. I. P. R. Company, in kindly placing their waiting-rooms at the several stations where they halted, at the disposal of the boys. The expense of this excursion is to be borne solely by Government. The amount allotted for the purpose of this excursion was 500 Rs."

THE following account of the Aurora of February 4 appears in the *Times of India* of the following day:—"A magnificent Aurora was visible, from the Rawul Pindie portion of the Punjab, last night, February 4, from 12 to past 12.30 o'clock. It occupied the northern quadrant of a clear sky, or rather more, the stars shining dimly through a glowing deep red hazy light reaching half way up the heavens, and which was crossed by thin vertical rays of white light stretching to the south. The night was calm but less frosty than usual at this season, and the oldest inhabitant who witnessed the display averred he had never seen anything like it in his life before." The suggestion made by our correspondent Mr. Earwaker, that we witnessed on that day a combination of the Northern and Southern Aurora, is thus confirmed.

SCIENCE IN PLAIN ENGLISH

IN a paper under this heading, in the *Boston Journal of Chemistry*, Mr. C. A. Joy, after quoting from our articles of June 22 and 29, 1871, proceeds thus:—"We must admit that what Mr. Rushton says of English schools applies equally well to our own. Does anybody know of a preparatory school in the United States where instruction in science is given on a systematic plan by teachers especially fitted for the work, and with well-selected apparatus and judicious text-books, and where an equal value for excellence in science is given to pupils as for mathematics and the languages? There are, doubtless, some such schools, but it is my misfortune never to have heard of them. The truth is, there are few teachers. The custom in this world of studying everything else but the world we live in, which has been handed down to us from our ancestors, has precluded the possibility of anybody being fitted to teach the natural sciences excepting the few who have had the energy and the means to overcome every obstacle, and to learn something; and they are so rare that they are not to be had for ordinary schools. We are now in a fair way to acquire considerable knowledge of the planet Mars, its climate and physical condition; and it may be that we shall some day be favoured by a visit from an inhabitant of that distant world. The arrival of such a visitor would be rapidly heralded over the land, and he would be introduced to our best society, to the leading men of education; and as he would doubtless be possessed of an inquiring turn of mind, he would have many embarrassing questions to ask. He might address the inquiry to the gentleman on his right at the public dinner, which would be sure to be given to him, as to the composition of the crust of the earth; or he might ask what the glass windows were made of, and what form of light shone through them, or the water on the table and the air of the room might absorb his attention. If the respondent happened to be a University bred man the chances are ten to one he could not answer a single question; he would be forced to say that the study of the language of a people formerly occupying a small portion of the globe had monopolised all of his time, and prevented the acquisition of a knowledge of any of the natural phenomena around him; he might, in fact, have more knowledge of Mars than of the earth. It is probable that our visitor would be slightly astonished at the ignorance of the best educated members of the community. I do not know that we are bound to prepare ourselves for the approaching visit, but the very suggestion of it ought to startle us a little out of our propriety, and make us review the course of instruction we have pursued for so many years. As long as the requirements for admission to college are left just as they are at present, all persons who expect to go to college must follow a prescribed course or be found wanting. The teacher in a preparatory school knows that the pupil can attend only a certain number of hours, and to get up his task for admission to college nearly all this time must be devoted to classical studies. There is no time left for science, and it is not taught. This state of things has led to a violent controversy on the part of the advocates of the two systems, and the question appears to be no nearer a solution at the present time than it was many years ago. The advocates of classical training will not yield an inch of ground, and the scientists are equally firm. It is a pity that some compromise cannot be effected, as a knowledge of Latin and Greek is of great value to the scientific student, and ought not to be omitted. And as the classicists now have the colleges in their power, would it not be well for them to recommend a knowledge of language rather than of grammar, and a facility of reading generally instead of prescribing the precise number of chapters and verses? If the teacher of Chemistry, for example, were to insist upon the students studying 100 pages of Miller, 50 pages of Roscoe, two books of Gerhardt, the correspondence of Lavoisier, and the life of Berzelius, before presenting himself for examination, he would be looked upon as slightly deranged; and yet this is precisely what is done by our classical friends. A chemist can tell in half an hour whether the candidate is prepared to go on with a certain class; and he cares not how, when, or where the applicant obtained the knowledge. Not so our classical friends; they insist upon chapter and verse as if there were a charm in the prescribed number—and by so doing they do great harm to our schools. A friend of mine desired to put his son at a select school, and had a long conversation with the principal in reference to the studies he would have to pursue in order to fit him for college. The principal had the experience of thirty years in his calling, and

know precisely what was required. He produced his scheme of hours, and convinced the parent that in order to fit his son for college it would be necessary for him to devote a certain number of hours to the reading of a prescribed number of pages and verses of Latin and Greek; and to do this no deduction could be safely made. He showed that the average attendance of boys was about 6,000 hours, and by assigning to each hour its particular work, if not interrupted by accident or illness, the pupil would be able to come up to the prescribed standard. My friend tried to see if a few minutes could not be gained for a small amount of science, but the teacher, with his experience of thirty years, was inexorable, and he could not crowd in a knowledge of this world into the course of studies even edgewise. It has been sometimes said that the most ignorant members of our community are our men of education; and after looking over the scheme of studies which the victims of liberal education are obliged to follow, the paradoxical remark would almost appear to be true. It may therefore be asked, What change the advocates of reform would propose? I cannot attempt to answer this question for all parties, as there is little uniformity of belief on the subject; but it may be well to state the case of a prominent party in the modern agitation. We have a large class among us who admit the culture to be derived from the study of language, and who would not on any account banish Latin and Greek from the curriculum; but they would remove that study to a later part of the course, and replace it by scientific subjects. They think that those subjects which cultivate and strengthen the powers of perception, observation, and judgment, should be taught first. They would instruct the youth in a knowledge of the laws of health or physiology; they would have him know something about plants, animals, minerals, and the commonest laws of chemistry and physics, so that if the pupil is compelled to leave school at an early age, he would know how to take care of mind and body, and be enabled to turn his knowledge to some account. They would commence the study of Latin and Greek at a period when the mind is more mature, and thus avoid the enormous waste of time, the bad habits of droning over lessons, and the monopolising character of the present system. There are so many instances of persons who commenced the study of the classics at mature years, who have excelled all others, that the advocates of postponing languages to the latter part of a boy's course appear to be justified in their claim. If the study of Latin and Greek could be commenced after the student enters college, it is believed that more real progress would be made in the four years of the college course than is effected under the present arrangement of devoting ten years of a boy's life to this study. This is the compromise that many good men advocate. They wish the preparatory schools to be wholly given up to mathematical, scientific, and English studies, and to have the colleges assume the charge of the classics. Instead of devoting every hour of the preparatory course to languages, they would give the time to the sciences, and they would demand a knowledge of the general principles of science as a requisite for admission to college. This would be turning the tables entirely, and would afford scientific men a chance to try the effect of the modern education. The other side have had it all their own way for a long time, and it would appear to be no more than fair for them to let people of different views have a chance. Such a radical change as this cannot be accomplished at once. It would demand immense moral courage on the part of the trustees of a college to expose themselves to the cry of lowering the standard of study. They would have the alumni of existing institutions and the prejudices of the whole community against them, and it would require a generation before the majority would become reconciled to the new order of things. Another obstacle would also arise at the outset, and that would be the difficulty of securing competent teachers of the natural sciences. It is this obstacle that has stood in the way of the introduction of the study of science in our schools. There are far too few teachers. To surmount this difficulty in the city of New York a normal college for females and a free college for males have been established, and scientific schools have been founded in all parts of the country. These institutions are destined to work a great revolution. As soon as they have trained a sufficient number of teachers, we shall find our public schools affording a better education than at present, and their example will have to be followed by the owners of private schools, who desire to keep up with the progress of the age. What we want is science taught in plain English, and there is every prospect of our speedily attaining the desired end."

SCIENTIFIC SERIALS

Numbers 8, 9, and 10 of the 27th volume of the *Proceedings of the Swedish Academy of Sciences* (Öfversigt af Kongl. Vetenskaps Akademiens Förhandlingar) which have just reached us, contain several valuable contributions to science. The most important of these relate to zoological subjects. Thus we find from M. Anton Stuxberg the first portion of a paper modestly described as a contribution to the Myriopodology of Scandinavia, but containing a synonymic revision, with descriptions, of the Swedish Chilognatha, under which the author recognises the genera *Tulus*, *Isobates*, *Blaniulus*, *Polydinus*, *Craspedosoma*, *Glomeris*, *Polyxenius*, and *Polyconium*, including in all eighteen species. M. G. Lindström contributes a paper on opercular structures in some recent and Silurian corals, in which he refers especially to *Goniophyllum pyramidalis* and *Cystiphyllum prismaticum*. From M. Gustaf Eisen we have a most valuable contribution to the Oligocephal fauna of Scandinavia illustrated with numerous figures on seven plates, and containing a monograph of the Scandinavian species of the genus *Lumbricus*, of which eight are recognised by the author. As the characters are given in Latin, and most of the species are found in this country, this paper will be of particular value to British naturalists. One species, *Lumbricus purpureus*, is described as new.—M. J. E. Areschoug communicates a list, with remarks, of a series of eggs collected by Dr. Hedenborg at Alexandria.—The longest paper is an account, by Prof. A. E. Nordenskiöld, of the Swedish Expedition to Greenland in 1870. This paper contains some interesting observations, illustrated with diagrams, on the glacial phenomena of Greenland; the remarks on the geology of the more interesting parts of the coast, especially those where fossil plants are found, are also of great importance; as is the account given of the supposed meteoric iron-stones of enormous size which have lately attracted so much attention. Analyses of the material of these masses by the authors, T. Nordström and J. Lindström, are given. Lists of the land plants and algae collected on the expedition, and of the microscopic algae obtained from the inland ice, form an appendix to the paper. M. P. T. Cleve contributes a paper on platinum-bases containing organic radicals, and M. G. R. Dahlander some investigations relating to the mechanical theory of heat.

The *American Naturalist* for January (vol. vi., No. 1) commences with Prof. Agassiz's letter, already printed in our columns, on Deep-sea Dredgings. Mr. F. W. Putnam follows, with an extremely interesting and well-illustrated article on the Blind Fishes of the Mammoth Cave of Kentucky, and their Allies, a sequel to Mr. Packard's paper on the Blind Insects of the same locality in the previous number. Dr. R. H. Ward describes a new erecting arrangement, especially designed for use with binocular microscopes. One of the most interesting articles in the number is on the Rattlesnake and Natural Selection, by Prof. N. S. Shaler, who, from observation of the animal in its native haunts, regards the rattle as a useful appendage, imitating the note of the Cicada, and thus attracting birds which are in the habit of preying on that insect. Prof. Shaler states that, without committing himself to a belief in the sufficiency of natural selection to account for the existence of the snake's rattle, he has been driven step by step from a decided opposition to the whole theory, and compelled to accept it as a *vera causa*, though still thinking it more limited in its action than Mr. Darwin believes. There is the usual supply of interesting short notes on the various branches of natural history.

Journal of the Scottish Meteorological Society, October 1871, New Series, No. xxxii.—This number of the Journal of the Scottish Meteorological Society contains a paper by Mr. Buchan, the secretary, "On the Rainfall of Scotland," based on observations made at forty-six places during long series of years. The questions of droughts and excessively wet years are dealt with. As regards their geographical distribution it is shown that some have been felt over the whole of Scotland, whilst others have been restricted to the west or to the east of the country, or within still narrower limits; and as regards their recurrence, that there has been no periodicity observed, and that there is nothing in the observations of the past forty years to sanction the opinion that there has been any progressive increase or decrease in the Scottish rainfall. The important engineering question of the deficiency of the three driest and the three driest consecutive years, in that estimating the rainfall of the three driest consecutive years, it will not be safe to deduct less than one-fourth from the

average annual rainfall. Mr. Buchan contributes another paper "On the Temperature of the Soil compared with that of the Air," being a discussion of series of observations made twelve times daily in different parts of Scotland, at the instance of the Marquis of Tweeddale, president of the society. From the observations it is seen that the surface temperature of the soil is considerably colder than the air resting on it in winter, and considerably warmer in summer; and from the relations of the temperature of the soil to that of the air during changes of weather, some interesting results are drawn with reference to the influence of solar and terrestrial radiation on climate.—A brief notice of the winter climate of Malaga, detailed notes of the weather of the quarter, and tabulated returns from ninety-one stations, including several highly important stations in Iceland, Faro, and regions bordering on the Mediterranean, make up the number.

Journal of the Chemical Society, December 1871.—This number commences with a paper by Watson Smith, "On the Distillation of Wood," and although of considerable technical interest it does not present any new features.—A paper on Anthralic Acid follows, by W. H. Perkin. This is a substance which occurs in the artificial alizarin of commerce. Two distinct formulæ have already been assigned to this body by Drs. Schunck and Liebermann. This communication proves conclusively that these formulæ were wrong, and that in reality this acid is isomeric with alizarin, but unlike that body it possesses no tinctorial power.—Dr. Armstrong contributes a paper on the action of Nitric Acid on the Dichlorophenol Sulphuric Acids. The results obtained are very interesting, but seem to cast some doubt on the theoretical speculations of some German chemists on the constitution of those bodies.—The abstracts in this number occupy 100 pages, and comprise many papers of great value.—E. Baudin has made an extensive series of experiments on the intimate action of substances which assist the decomposition of potassic chlorate and the disengagement of oxygen. Many bodies were tried, some of which, as cupric or manganic oxides, when heated with potassic chlorate, as is well known, yield oxygen very readily, in this case, when the temperature reaches a definite point, a sudden rise of 50° or 60° takes place with a tumultuous evolution of gas. The author has found that the decomposition of potassic chlorate is always accompanied with a disengagement of heat, so that this substance may be called an endothermic compound.

The Monthly Microscopical Journal, February 1872.—"On the relation of Nerves to Pigment and other Cells or Elementary Parts," by Dr. Lionel S. Beale, F.R.S. After alluding to the tendency of opinion in these days to favour the conclusion that the finest branches of nerve fibres come into structural relation with the active elements of other tissues, Dr. Beale affirmed his opinion that, whatever may be the influence produced by the nerves upon the structure, he does not think it depends upon continuity of substance between the nerve and the tissue affected.—"Report on Slides of Insect Scales," sent to the Royal Microscopical Society by the Chevalier de Cerbacq, examined by Henry J. Slack.—"On the Structure of the Stems of the Arborescent *Lycopodiaceæ* of the Coal Measures," by W. Carruthers, F.R.S.—"On a Leaf-Bearing Branch of a Species of *Lepidodendron*." These papers contain the results of an examination of a series of specimens from Mr. John Butterworth, of Shaw, near Oldham.—"On Bog Mosses," by Dr. R. Braithwaite, F.R.S., part iii., Monograph of the European species. This paper includes an enumeration of species, and full description of *Sphagnum cymbifolium*, the first in the series.—"The advancing powers of Microscopic Definition," by Dr. Royston Piggott. This is a further contribution to the vexed question of beaded scales, and may be taken as a summary of Dr. Royston Piggott's views, of which the first portion appears in the present number of the journal.—"Microscopical Object-glasses and their Power," by Edwin Bicknell.—"Remarks on a Tolles' Immersion," by Edwin Bicknell.—"Maltwood's Finder Supplemented," by W. K. Bridgman. This latter communication offers a plan by means of which two correspondents may bring their "Maltwoods" into relation with each other, supposing that their indications do not coincide.—"On a new Micro-telescope," by Prof. R. H. Ward, reprinted from the "American Naturalist." This number of the journal is illustrated by four plates.

The Journal of Botany for February is ornamented by a very good portrait of the late editor, Dr. Berthold Seemann. The original articles are fewer than usual, including only the conclu-

sion of Mr. J. G. Baker's paper on the Botany of the Lizard Peninsula, and a case of poisoning by the seeds of *Macrosamia spiralis*, by Dr. George Bennett. There are, however, a good many interesting short notes and several valuable reprints, including Dr. W. R. McNab's Histological Notes, read before the Botanical Society of Edinburgh; a list of new species of phanerogamous plants published in Great Britain in the year 1871 in the *Annals and Magazine of Natural History*, *Botanical Magazine*, *Floral Magazine*, *Gardeners' Chronicle*, *Hooker's Icones Plantarum*, *Journal of Botany*, *Journal of the Linnean Society*, and *Refugium Botanicum*; and Canon Kingsley's admirable address to the Winchester and Hampshire Scientific and Literary Society, on Bio-Geology.

SOCIETIES AND ACADEMIES

LONDON

Geological Society, February 21.—Prof. Ramsay, F.R.S., vice-president, in the chair. The following communication was read:—"Migrations of the Graptolites." By Prof. H. Alleyne Nicholson, M.D. The author commenced by stating that the occurrence of the same species of marine animals in deposits in different areas is now generally regarded as evidence that such deposits are not strictly contemporaneous, but rather that a migration from one area to another has taken place; this migration he thought would probably in many cases be accompanied by modification. Applying these principles to the Graptolites, he endeavoured to show in what directions their migrations may have taken place. He excluded from the family Graptolite the genera *Dictyonema*, *Dendrograptus*, *Collargraptus*, and *Ptilograptus*, and stated that the family as thus limited extended from Upper Cambrian to Upper Silurian times. The earliest known Graptolites were those of the Skiddaw Slates, which he thought would prove to belong to the Upper Cambrian series. The Skiddaw area he considered to extend into Canada, where the Quebec group belongs to it. Genera of Graptolites belonging to this area are represented in Australia, and this the author regarded as indicative of migration, but in which direction was uncertain. Having discussed the forms of Graptolites characteristic of the deposits in the Skiddaw-Quebec area, the author proceeded to indicate the mode in which the family is represented in the areas of deposition of the great Silurian series, namely, the Llandoilley areas of Wales and Scotland, the Coniston area of the North of England, the Gala area of South Scotland, the Hudson-River area of North America, and the Saxon and Bohemian areas, giving under each of these heads a list of species, with indications of their probable derivation. Mr. Etheridge commented on the importance of Dr. Nicholson's paper, and on the difficulties attending the study of the Graptolite. The migration of these organisms appeared to him to be very difficult to establish, especially in connection with their extension both eastwards and westwards. Mr. Hughes believed that if we could discover the original of any species, we should see a small variety appearing among a number of forms not very different from it, and from which it had been derived; but when the variety had prevailed, so as to be the dominant form, we were far on in the history of the species; that it was a great assumption to fix upon any bed we now know as representing the original source of any group; that we know too little about the chronological order of the geological divisions referred to to reason with any safety on the migration of Graptolites from one era to another; that the term *Lower* Llandoilley, for instance, was very unsatisfactory as used in the paper; there was nothing lower than the Llandoilley Flags at Llandoilley; and where older beds occurred in Scotland and elsewhere, it was not at all clear that the equivalent of the Llandoilley Flags was present at all. He differed also altogether from the author as to the position of the Dufton Shales, and criticised the views of the author as to the range of some species. He thought that M. Barrande's theory of the colonies was borne out by the study of the Graptolites, but that we had not sufficient data to speculate as to the areas in which they made their first appearance, or the order of their geographical distribution. Prof. Duncan observed that at the present time there was, among other forms, quite as great a range for species as that of the Graptolites pointed out by the author. Having looked through all the drawings of Graptolites that he could meet with, he had found none whatever that were accurate; and he had moreover never in any specimens discovered such cups or *calices* between the

serrations as were always attributed to these organisms. From all he had seen he was led to the conclusion that the projections on the Graptolites bore the same relation to the central stem as those of some of the Actinozoa. These latter also, like the Graptolites, seemed to prefer a muddy sea. Professor Duncan also suggested that the Graptolites were really the remains of the filiform polypterous parts of floating Hydrozoa. Prof. Morris regarded the paper as mainly suggestive. It was on all hands agreed that there were in Britain two principal zones in which graptolitic life was most abundant; and the same held good in America. Both these seemed to be homotaxially related. M. Barrande had long since pointed out the probable emigration of many of the Bohemian species from the British area; and there could be no doubt of there being many species common to Europe, America, and Australia. This afforded strong evidence in favour of some such theory as that of migration. He cautioned observers as to taking careful notice of the manner in which Graptolites are presented in their matrix; for when seen from three different points of view, they exhibited such differences that three species might be made from one form of organism. Mr. Gwyn Jeffreys mentioned the wide distribution of marine Hydrozoa by means of winds and currents, as illustrative of the history of Graptolites, the dispersion of which might have arisen from similar cause, and not from migration. Mr. Prestwich commented on the uncertainty of our knowledge with regard to Graptolites, and consequently regarded speculation on the subject of their migration as premature. He instanced *Cardita planicostata*, which was formerly regarded as having originated in the Paris basin and come thence into England, but which had since been found in far earlier beds in Britain; so that the presumed course of its migration had been reversed. Mr. Hicks remarked that the rocks referred by the author to the Upper Cambrian were in reality the lowest of the Silurian series, and that the Graptolites were exclusively a Silurian family. Mr. Hopkinson also made some remarks both on the distinction of different species of Graptolites and on their distribution. He regarded the Quebec area as that in which these forms had originated. The Chairman commented on the great want of accord among those who had studied Graptolites, not only with regard to their structure, but to their distribution in different horizons. He thought that the suggestion of the author, as to modification of form during migration having taken place, seemed to throw some light on the subject. He could not regard two districts now only separated by the Solway Firth as constituting two geographical areas so distinct that the occurrence of the same species in both could with propriety be held to be due to migration. The phenomena in the other cases seemed to him quite as much in accordance with distribution from some common centre as with migration along any line connecting two spots where Graptolites are now found. He thought that the recurrence of these forms on different horizons in Cumberland was to be accounted for by the fact that most of the rocks which intervened between the shales containing these organisms were merely sub-aerial volcanic beds, on which, after submergence, these muddy shales had been deposited.

Entomological Society, February 19.—Prof. J. O. Westwood, president, in the chair.—Drs. Ransome and Livett, and Messrs. Rothera and Jenner, were elected subscribers to the society.—Mr. F. Smith made some observations respecting the occurrence of two pupæ in one large common cocoon of *Bombyx mori* from China. The examples had been found amongst silk-waste in a London warehouse, and this waste had been attacked by mice, which fed upon the dead chrysalides. He further remarked that, occasionally, two or more swarms of wasps united in building a common nest, and also that broods of different species of wasps could be induced to act in concert, the result being that when these wasps used different building materials, a parti-coloured nest was produced.—Mr. Butler exhibited drawings of a large grub, apparently the larva of some species of Ichneumonidae, which had emerged from the larva of the common "buff-tip" moth (*Pygæra bucephala*), which it nearly equalled in size.—Dr. Buchanan White communicated extracts from his note-book respecting the habits of a species of ant as observed at Capri in 1866, confirming Mr. Moggridge's recent observations as to the grain-storing habits of these ants. Mr. Horne had observed a similar habit in certain Indian ants.—Prof Westwood exhibited type-specimens and drawings of the animal from Madagascar, upon which Latreille founded his genus *Protopsisoma* as pertaining to the *Crustacea*; and made some remarks thereon connected with the assertion of a French entomologist,

Dr. Joly, that these creatures, and "le Binocle" of the neighbourhood of Paris, described by Geoffroy, are in reality the earlier stages of species of *Ephemeride*. Prof. Westwood was scarcely able to believe that this association was founded upon facts, though he was not disposed to express any opinion as to their actual affinities.—Mr. Müller read some remarks on the habits of certain gall-producing saw-flies of the willow, which are said to avoid those portions of the trees that overhang water, and suggested a practical application of the theory to save choice fruit-trees from the attacks of insects, by surrounding them with glass at the base, it being well known that glass is often mistaken for water by aquatic insects.

Anthropological Institute, February 19.—Sir John Lubbock, Bart., F.R.S., president, in the chair. Messrs. C. Bowley, R. J. Nunn, Edward Harris, J. E. Price, and J. P. Steele, were elected members. Mr. H. H. Howorth read a paper entitled "Strictures on Darwinism. Part I.: Fertility and Sterility." After a brief statement of the evolutionary theory of Mr. Darwin, which was the old-fashioned theory of Malthus pressed to its utmost limits, viz., that in the struggle for existence which is always going on everywhere the weak elements go to the wall and are gradually eliminated whilst the strong survive, the author stated his intention in the present paper to confine his examination to one case in its concrete form. He criticised the argument that physical vigour, health, and strength had, in the struggle for existence, a tendency to prevail to the expulsion and eradication of weakness and debility, and he held that the reverse was the truth as regarded the large majority of cases, and the paradox was the same in substance as that maintained by Mr. Doubleday in his true Law of Population. It was shown that the gardener, who was an empirical philosopher, in his experience of cultivated plants, was fully aware of the truth of the principle advocated by the author, and a great number of instances were cited in illustration. Passing from the vegetable to the animal world, he showed how stock-keepers and breeders had accumulated much sound experience, which corroborated that of the gardener in regard to plants. It was a golden rule with them to keep their animals weak and in a state of depletion if they wished them to breed freely. Pure breeds were seldom very fruitful, they were notoriously pampered and highly fed; but when turned into coarse and scanty pastures their rounded sides became denuded of flesh and the animals bred more freely. The same principle obtained with man. It was in the crowded alleys and among half-starved or ill-fed populations that fertility was greatest. The author had high authority for stating that as a general rule convalescent persons—those recovering from prostrating diseases—were very fertile. On the other hand, with the rich and well-to-do, especially among families whose position for some generations had been prosperous, comparative sterility prevailed. Illustrations of that dictum were drawn from the writings of physiologists, from statistics, from the genealogical histories of the nobility and gentry, and were sustained by lengthened argument. National and ethnic tendencies to fertility or sterility were surveyed by the author, e.g., among the Irish, various Black and savage peoples, Americans aboriginal and modern, the Slaves, and various Russian tribes. In conclusion, the arguments were thus summarised: that sterility is induced by vigorous health and by a plentiful supply of the necessities of life, while fertility is induced by want and debility, and that this law acts directly against Mr. Darwin's theory, inasmuch as it is constantly recruiting the weak and decrepit at the expense of the hearty and vigorous, and is thus persistently working against the favourite scheme of Mr. Darwin, that in the struggle for existence the weak are always being eliminated by the strong.

MANCHESTER

Literary and Philosophical Society, February 20.—Mr. E. W. Binney, F.R.S., president, in the chair. The president said that at the meeting of the society on the 9th of January last he alluded to the probability of the genus *Zygopterus* being found in the limestone nodules of the Foot Mine near Oldham. He had lately had an opportunity of inspecting the collection of Mr. James Whitaker of Watershedding, and he there recognised a specimen of the *Zygopterus Lacatili* of Mr. Regnalt. There was a difference between the Autun and Oldham specimens; for whilst the vascular bundles in the petiole of the former were shaped like a double anchor, in the latter they came nearly together and formed a circle; but he thought this difference scarcely sufficient to form another species.—Dr. J. P. Joulé, F.R.S., described some experiments he had been making

on the polarisation by frictional electricity of platina plates, either immersed in water or rolled together with wet silk intervening. The charge was only diminished one half after an interval of an hour and a quarter. It was ascertained both in quality and quantity by transmitting it through a delicate galvanometer. He suggested that a condenser on this principle might be useful for the observation of atmospheric electricity.—“On an Electrical Corona resembling the Solar Corona,” by Prof. Osborne Reynolds.—“On the Electro-Dynamic effect, the induction of Static Electricity causes in a moving body. The induction of the Sun a probable cause of Terrestrial Magnetism,” by Prof. Osborne Reynolds.

EDINBURGH

Royal Physical Society, February 28.—Dr. James M'Bain, president, in the chair. The following communications were read:—“On the Dentition of *Echinorhinus spinosus*,” by Prof. Duns. Dr. Duns has obtained two specimens of this rare shark in the Firth of Forth, one in 1868 and another in 1871. The former is in the Scottish Natural Museum, the latter in the Museum of the New College. The specimens noticed by Yarrell were referred to, and the form of the teeth of the 1868 example shown. The remarks of Agassiz were quoted on the resemblance of the teeth of *Echinorhinus* to those of his genus *Goniodus*. It was shown, that while in other specific features the specimen of 1871 resembles those of that got in 1868, it differs very widely in the form of the teeth.—“On Garnetiferous Limestone, Balmoral,” by Prof. Duns.—“On the Preservation of Compound Ascidiæ,” by Mr. C. W. Peach. Mr. Peach stated that when living at Cornwall he was much struck by the beauty of the compound ascidiæ, so abundant on rocks, &c., between tide-marks there, and that he was perfectly aware that the beauty of the colours and flower-like systems of these lovely objects was always lost, whether they were preserved in spirits or any other fluid. He thought of Canada balsam—the great difficulty of contending with wet objects suggested itself. He, however, tried, and so far succeeded, by laying them on glass, (when detached from the rocks), after squeezing out as much as possible of the moisture by first laying them in cotton or linen rag between sheets of blotting paper, changing these as often as required, and doing all as quickly as possible, after taking the object from the sea. Thus dried, they were placed on glass covered with warmed Canada balsam, and covered with another similarly prepared plate of glass, on which sufficient balsam was melted to cover up completely the specimen. It is then allowed to cool under slight pressure, the superfluous balsam scraped off, and sealing-wax put round the edges to form a cell, and thus they were preserved. He exhibited several specimens—some preserved twenty-five years ago—of *Leptoclinum*, *Botryllus*, *Didemnum*, *Paracirra*, &c., in a beautifully preserved condition.—Mr. Peach exhibited a number of fossil plants he had collected last summer from the coal-fields of Edinburgh, Slamannan, Bathgate, and Devonside near Tillicoultry.—“On the Phosphate Deposits of South Carolina,” by Prof. Pratt, Charleston, U.S.—Mr. John Hunter exhibited a series of fossils from the same region.

DUBLIN

Royal Irish Academy, February 12.—Rev. J. H. Jellett, president, in the chair. Dr Eugene A. Connell read a paper on the identification of the ancient Cemetery at Loughcrew, Co. Meath.—Dr. W. Frazer read notes on several finds of silver coins lately made in Ireland.

PARIS

Academy of Sciences, February 19.—The dispute concerning the accuracy of the results published by the Paris Observatory was carried on rather briskly by MM. Serret, Le Verrier and Delaunay.—A note by M. Zeuthen on the determination of the characteristics of the elementary systems of cubics was presented, with remarks by M. Chasles.—M. Ciotti claimed the originality of his researches on the employment of vibratory elastic laminae as a means of propulsion.—M. Delaunay communicated some remarks on the experiments of M. Wolf, on the reflecting power of silvered glass mirrors.—Numerous reports on the aurora of February 4 were presented, and also a note by Marshal Vaillant on the phenomena which give rise to auroras, a note by M. H. Tarry on the origin of polar auroras, and a memoir by M. Silbermann on the facts from which we may deduce a theory of auroræ borealis and australis founded on the

existence of atmospheric tides, and the indication, by means of auroras, of the existence of flights of meteors in proximity to the terrestrial globe.—Marshal Vaillant regarded auroras as produced by the reflection from the surface of the terrestrial atmosphere of the light produced by electrical or magnetic currents. M. Tarry ascribes to these phenomena a cosmical origin.—A note by M. J. L. Soret on the induction currents produced in the coils of an electro-magnet when a metallic mass is set in rotation between its poles was read.—M. H. Sainte-Claire Deville presented a note by M. E. Branley on the measurement of the polarisation in a voltaic element.—A note by M. Respighi on the spectral analysis of the zodiacal light was read, in which the author detailed some interesting observations on the spectral phenomena presented by the zodiacal light and auroras tending to indicate the identity of origin of the two phenomena.—M. Delaunay presented a note by MM. Loewy and Tisserand on the search for the last planet (99) Dike.—MM. J. Pierre and E. Puchot communicated some facts in the history of propyl alcohol, relating chiefly to the behaviour under distillation of the so-called monohydrate of that body.—M. G. Tissandier communicated a note on a new mode of producing anhydrous protoxide of iron by the action of carbonic acid upon iron heated to redness. The author describes the properties of the oxide thus prepared.—A memoir was read by M. E. Duclaux, on iodide of starch, which he does not regard as a regular chemical compound.—A note by M. Blondlot on the alcoholic fermentation of sugar of milk was read. The author described the fermentation of milk when agitated from time to time, by means of a ferment apparently proper to it, and stated that this fermentation was continued by the addition of sugar of milk or glucose to the fluid after the cessation of the first fermentation. He obtained alcohol by the distillation of the fermented product, and regarded his results as favourable to the theory of fermentation of M. Pasteur.—M. Pasteur criticised the recent communications of M. Fremy on the subject of fermentation, discussing his experiments *seriatim*, and indicating objections to them.—M. S. de Luca presented some investigations upon the composition of the gases which are evolved from the fumaroles of the solfatara of Pozzuoli, upon which M. Boussingault made some remarks.—The processes for the preservation of wines by the application of heat formed the subject of notes by M. A. de Vergnette-Lamotte and by Dr. Bart.—M. E. Alix noticed the existence of the depressor nerve in the hippopotamus, and stated that it resembles that of the horse in arrangement, but is thinner coinciding with the small size of the primitive carotid.—M. A. Béchamp presented some observations on a recent note by M. de Segnes upon microzymes.

February 26.—The following mathematical papers were read:—An exposition of a geometric theory of the curvature of surfaces, by M. A. Mannheim, presented by M. Serret; a note on some relations between the angular quantities of convex polyhedra, by M. L. Lalanne; and a determination of the characteristics of the elementary systems of cubics, by M. Zeuthen, communicated by M. Chasles.—M. de Saint Venant read a memoir on the hydrodynamics of streams.—M. Phillips presented a note on the governing spiral of chronometers, and M. de Pambour a second paper on the theory of hydraulic wheels, relating to the reaction wheel.—A letter from Father Secchi on the aurora of February 4, and on some new results of spectrum analysis, was read, containing a description of the appearances observed at Rome, with a notice of the phenomena presented by spectrum analysis, and a discussion of the supposed relation between auroras and the solar protuberances, which the author is not inclined to accept. In a postscript M. Secchi calls attention to the appearance of remarkably distinct bands and lines upon the planet Jupiter.—A communication was read from Prof. Piazzi Smyth, on the brilliant yellow band in the spectrum of auroras, which he stated to be of constant occurrence, and to fall always upon the line 5579.—M. A. Laussedat also presented a memoir on the aurora of February 4, and M. C. Sainte-Claire Deville a continuation of M. J. Silbermann's memoir on the theory of auroras, and on the indication by their means of the existence of flights of asteroids in proximity to the earth.—M. C. Sainte-Claire Deville also read a note on the probable application of quadruple, dodecuple, and tridodecuple symmetries, or of periods of 90, 30, and 10 days, to the mean returns of the electrical phenomena of the atmosphere, such as storms and auroras.—M. E. Becquerel presented a memoir by M. G. Planté, on the employment of secondary currents to accumulate or transform the effects of the galvanic battery, containing the description of improvements in

the arrangements previously suggested by him.—M. H. Sainte-Claire Deville communicated a note by M. J. M. Gauguin on the electromotor forces developed by the contact of metals with inactive fluids, containing the discussion of results obtained with plates of platinum in distilled water.—The question of priority in the invention of the method of preserving wines by the action of heat was treated at some length by M. Balard, to whom M. Thenard replied.—M. Tellier forwarded a further communication on his system of producing cold by the evaporation of ether, assisted by compressed air.—M. Wurtz presented a note by M. E. Reboul on two new isomers of bromide of propylene.—M. J. Personne read a note on iodide of starch, in answer to one presented by M. Duclaux at the last meeting. M. Personne claims to have arrived six years ago at the conclusion that the so-called iodide of starch is not a chemical compound.—A note by M. Marey, on the determination of the inclinations of the plane of the wing at different moments of its revolution was read.—M. C. Bernard presented a third note by M. P. Bert on the influence which changes in barometric pressure exert upon the phenomena of life, in which the author described the effects produced by exposing small animals to various degrees of atmospheric pressure. He has found that up to a pressure of two atmospheres sparrows die when the air in the receiver contains 25 per cent. of carbonic acid, but that above this limit and below a pressure of 25 centims., this law does not apply. In the former case the birds perish partly by the toxic effects of an excess of oxygen, and in the latter by a privation of oxygen.—M. C. Bernard also communicated a note by M. N. Gréhan on the respiration of fishes, containing a statement of the curious fact that fishes in respiration can avail themselves not only of the oxygen dissolved in the water, but also of that held by the red corpuscles of the blood of other animals when these are mixed with the water.—A note by MM. L. Labbé and G. Guyon on the combined action of morphine and chloroform, was also presented by M. C. Bernard. The authors state that a state of perfect anaesthesia may be produced and sustained for a long time without the usual danger, by administering a subcutaneous injection of hydrochlorate of morphine about a quarter of an hour before the exhibition of chloroform.—M. A. Béchamp read a paper "On the Essential Nature of the Organised Corpuscles of the Atmosphere, and on the part which belongs to them in the phenomena of Fermentation."—M. S. Meunier presented a note on the existence of bauxite in French Guiana.

VIENNA

Geological Institution, February 6.—Dr. Neumayr, "On the Jurassic Provinces of Europe." The author stated the different development of the Jurassic strata in three regions of Europe. To the Mediterranean province belong the Jurassic beds of Spain, and of the Alpine and Carpathian districts; secondly, the middle European province is formed by the Jurassic beds of England, France, and Northern Germany; while to the third, the Russian province, belong the Jurassic beds of Russia, as well as those of Spitzbergen and Greenland. The only really important diversity between the Jurassic strata of these provinces is founded, as he shows, on differences in the zoological characters of their faunas. Thus, for instance, the most prevalent peculiarity of the Mediterranean province is the presence of Ammonites of the two genera, *Phylloceras* (*Icterophyllus*) and *Lytoceras* (*Fimbriatus*), which abound in almost all members of the Jurassic formation in the Alps and Carpathians, while they are almost entirely wanting in the middle European province. The Russian province, on the contrary, is chiefly characterised by the absence of reef-forming coral and some other peculiarities. It is impossible to account for this difference by the supposition of land having separated the Jurassic seas of the different provinces. The fact that along the line of separation between the Mediterranean and middle European provinces, from the South of France to the Crimea, strata of both provinces approach very near, even to a few miles, excludes this supposition. The only possible mode of explanation the author finds in accepting in the Jurassic period climatic differences in the zones from north to south. The strict separation of both faunas along the said line may be explained, he thinks, by a great stream of warm water, which produced similar effects to the Gulf Stream in our time.—Dr. G. Pilar, "On the Tertiary deposits in the valley of the Culpa, in the environs of Glin, in Croatia." Very instructive sections have been denuded in these deposits by the Culpa river. The marine beds, as well as the Sarmatic and the Congeria beds are developed; all abound with fossils.

LA SEINE*

IN carrying out the great works for the improvement and embellishment of Paris under the late Empire, all incidental discoveries of objects relating to art, history, and science, were systematically investigated, recorded, and preserved, instead of being left to the chance and uncertain description of casual and independent observers. In a liberal and enlightened spirit the Municipality of Paris and the Préfet de la Seine (M. Haussmann) established a proper organisation and a staff (*Service des fouilles et des substructions*) to follow up such discoveries, to take plans of old works, to preserve all art treasures or objects of scientific value; to note, in fact, and to investigate everything of interest. Men eminent in several departments were consulted, and engaged to draw up reports with full illustrations of the discoveries. By these judicious measures, the knowledge of the topography, antiquities, and archaeology of Old Paris has been greatly advanced. Works of the Roman, Gallic, and Mediæval periods have been brought to light, surveys and plans made, and the more important specimens preserved *in situ* or in the public museums.

To M. Belgrand, the eminent and able engineer for the water supply and drainage of Paris, was deputed the work of recording all the geological and some of the archaeological facts discovered during the construction of the large works on which he was engaged.

Paris up to the last few years had been supplied with water from local sources (river, canal, and wells), but as these were found insufficient and of indifferent quality, it was determined to seek for other and better sources of supply at a distance, and some large springs in the chalk district, respectively distant sixty and eighty-four miles from Paris, were eventually selected by M. Belgrand, and their waters were brought to Paris by means of aqueducts on a high level. In carrying out this great work, M. Belgrand made himself intimately acquainted with the hydrography of the Basin of the Seine. He explored every valley, and determined the *régime* of every important river. The result of the first part of the inquiry appeared in a valuable series of tables, showing the connection between the rainfall and the discharge of each river—the extent and nature of the floods, and the geological character of the ground with reference to the range and extent of the permeable and impermeable strata, and which he illustrated by a specially coloured map. In connection with the construction of the aqueducts, M. Belgrand had also to ascertain the nature of the surface and the contours of the hills and great plains along which he carried them, and to examine the many pits whence the materials for construction were obtained. This geological investigation led to the discovery of many interesting specimens, and further suggested many theoretical inquiries relating to the origin of the present surface, and to the *régime* of the old Seine during the later geological periods. The result of the in-

quiry is embodied in the three handsome quarto volumes before us—one of 255 pages of text, with 105 pages of introduction, descriptive of the country and giving the theoretical views; a second containing plates of fossils, of flint implements, and pit sections; and a third with extended coloured sections and a monograph by M. Bourguignat of the shells found in the Drift beds.

Paris stands on Tertiary strata, from beneath which, at a distance of some miles, the chalk crops out and forms a belt many miles in width. These formations constitute a table land having a height of 100 to 200 feet along the sea coast of Normandy, and rising from 500 to 600 feet inland in Champagne. This district is traversed by the Seine and its tributaries, flowing in comparatively narrow valleys cut deep into the table land; while, on the extended upland plains thus formed, there rise, here and there, ranges of hills of Fontainebleau Sands or other later Tertiary strata. The strike of these hills is in a direction entirely distinct from that of the hill slopes flanking the river valleys and forming part of the present river-system. The latter range in various directions—north, north-east, south, and south-east—in accordance with the direction of the tributaries of the Seine until they join that river, the main channel of which has, from Montereau to the sea, a general direction south-east to north-west. M. Belgrand found that the hills on the plains nearly all ranged in this one given direction, or approximately from south-east to north-west, with intervening valleys having the same direction. Numerous such ridges, none being of any great length and all narrow and having this definite trend, are found to extend over the whole plateau area uninfluenced by the more tortuous deeper river-valleys which intersect the same area at various angles to their course. The river-valleys are covered with gravel formed of the *débris* of the rocks through which the present rivers flow, while the plateau valleys and plains are free from such *débris*, but are covered with a uniform layer of red clay or loam. Whence M. Belgrand concludes that the two systems of valleys have a different origin. He contends that it is not possible to have a true river channel without having more or less drifted gravels formed by the constant action of running water and by floods, and therefore that these higher valleys could not have been formed by river action, while at the same time their rectilinear and special bearing indicates that their formation is due to one common and independent cause.

M. Belgrand considers that the only explanation which will account for the phenomena presented by these higher-level valleys and hills, is the rapid and transient passage of a large body of water over the surface; and as the excavation of these higher valleys took place after the formation of the Fontainebleau Sands and of the Calcaire de Beauce (Miocene), and before the Pliocene period (for the *Elephas meridionalis* of the valley of the Eure shows that the land had then emerged), and as also, according to M. Elie de Beaumont, the elevation of the main chain of the Alps took place at the same period, M. Belgrand connects the two events and supposes that the sea of the Pliocene deposits of the Alpine area was thereby displaced and that it swept over this northern portion of France, denuding the softer portions of the strata and leaving narrow ridges of the harder portions

* *Le Bassin Parisien aux Ages Antéhistoriques*. Par M. Belgrand, Inspecteur-Général des Ponts et Chaussées, Directeur des Eaux et des Egoûts de la Ville de Paris. (Paris: Imprimerie Impériale.)

all trending south-east to north-west (or in the direction from the Alps), standing out, on the denuded high plains, as monuments of its passage. M. Belgrand points out that where the Tertiary strata have presented a resistance which the waters could not overcome, the high-level valleys formed by the diluvial waters are, in such cases, fronted in the opposite range of hills, against which the mass of waters impinged, by a deep bay cut by the current in those hills, and that the waters thus checked in their course were turned off at acute angles, until they reached the main channel of the Seine, tending thereby to form secondary or tributary valleys, which, when the deluge had passed, contributed, with the Seine valley, to form the present lines of river drainage. Such volumes of water as we have depicted would, he argues, have swept the higher channels and plains clear of *débris*, leaving the denuded area covered merely with the silt thrown down from muddy waters, and depositing the coarser *débris* in the middle and lower range of the deeper channels through which the present rivers afterwards took their course. In support of this hypothesis, he shows that, whereas the basin of the Seine is now drained by the one river and its tributaries, the diluvial waters held their course straight across that basin and debouched in five main channels—one, marked by the hills of Montmorency and Satory, took the course of the Seine below Montereau to the sea, but in a more direct and broader line; the second took the course shown by the hills of Villers-Cotterets, thence across the present valley of the Oise, along the valley of the Pays de Bray, to the sea at Dieppe; the third followed in part the course of the Aisne, and then by the line of the Somme valley to the sea; and the fourth and fifth by those of the valleys of the Aulthie and Cauche. M. Belgrand accounts for the rapidity and force of this cataclysm in the belief, which he shares with M. Elie de Beaumont, that the elevation of the Alps took place rapidly and suddenly.

But there was a second elevation of the Alps, at a later geological period, and which, according to M. Belgrand, may have produced a second deluge, not by the displacement of the sea, for then there were only lakes on the north-western side of those mountains, but by the sudden melting of the snow on that great range; and our author again adopts the views of M. Elie de Beaumont on this subject. This distinguished geologist propounded in 1847 the theory that that last convulsion of the Alps was accompanied by an enormous disengagement of those gases to which has been attributed the formation of the Dolomites and Gypsum beds of that chain, and that this caused the accumulated snows to melt in a very brief period of time (*un instant*). At the same time, according to the same authority, the Pliocene lakes of "La Bresse" were raised and drained. Thus, suggests M. Belgrand, this second convulsion might have caused another diluvial wave to pass over the basin of the Seine—an hypothesis also advanced by M. Elie de Beaumont, who speaks of "the probable concurrence in this off-throw flood (*d'éversement*) towards the north-west, of the waters of the great lake of La Bresse, in the production of the diluvial phenomena observed in the neighbourhood of Paris."

We are disposed to agree with our author in the opinion, which we have elsewhere expressed, that the original contour of the surface with its higher valleys

and hills, is due to a cause different from that which excavated the present river valleys—that it preceded and is independent of it—but we cannot agree with him as to the nature of that cause. Without going far into the argument, we may mention that the well-known fact of the gravel found in each tributary of the valley of the Seine, consisting of the *débris* of those rocks only through which that tributary flows, while in the Seine valley are found the *débris* of all the tributaries, together with its own and no more, is, it seems to us, a conclusive argument against the passage of a body of water from one great basin to another—against the flow of such a body of water from the Alps across the Jura, the great plains of the Doubs and the Soane, the southern prolongation of the Vosges, and, over the separating water-shed formed by the lower hills of Burgundy, to the Seine basin, and so to sea on the northern shores of France. Such a cataclysm must surely have spread the *débris* of the strata destroyed in its course north-westward along the tract over which it flowed. Some remains of the rocks of Switzerland, of those of the Vosges and of Burgundy, must surely have been detected in the course of its passage. How can the author account for the large blocks and abundant *débris* of the Seine valley—which blocks and *débris* he considers as originally due to this cataclysmic action—and yet overlook the almost necessary consequence of the introduction of some foreign elements into the Seine Basin, whereas none such exist. Not only is the *débris* of each great basin restricted to its own rocks, but even each tributary river valley has its own special rock *débris* and no other. M. Belgrand remarks, it is true, of the Somme Valley, which lies on the line of his third great diluvial water channel, and which prolonged south-east passes across the Oise valley and up that of the Aisne, that some *débris* of the older rocks of the latter areas have been found in the chalk valley of the Somme. But we must confess we have never found a trace of such a mixture, and we have particularly examined the Drift of those areas with a view to the determination of this point. At the same time the watershed between the two valleys is so low that their complete separation in old times appears to us more remarkable than their present independence, and we can quite conceive the possibility of the Oise waters, when that river flowed at its higher level, passing at periods of flood into the valley of the Somme, and so carrying some small amount of *débris* across the present water-shed, especially as so good an observer as M. Buteux is referred to as the authority for this fact. If there, however, it is evidently quite the exception, and may be accounted for as just suggested.

With regard to the ingenious suggestion of M. Belgrand that some south-east and north-west valleys of the tablelands are faced on the opposite side of intersecting river valleys by a bay in the hills due to the violence of the checked diluvial waters, such for example as the amphitheatre in the hills on the west of the River Ecolle between Milly and Moigny and again at Soissy, it is to be remarked that such amphitheatres exist equally on the opposite or lee side of the hills towards La Ferté-Aleps and Maise; and, further, that, in the same Tertiary area beyond the intersecting range of hills between the Ecolle and the Essonne (which according to M. Belgrand's views

should have acted as a breakwater), the south-east and north-west ridges again resume between the valleys of the Essonne and the Eure.

After the contour of the surface produced by this cat-
clysm, and by which M. Belgrand considers that all traces
of any previous river courses must have been obliterated,
the Seine and its tributaries began to flow at an elevation
estimated by him of from 80 to 100 feet above the present
level. This he proves, as we have already done, by the
occurrence of the remains of land mammalia and of river
and land shells in beds of Drift at that elevation above
the Seine on some of the hills near Paris. This part of
M. Belgrand's work is admirably illustrated, both by
general and local sections, and contains valuable lists of
the mammalian remains, in the determination of which
he had the advantage of the high authority of the late
M. Ed. Lartet. Here again we cannot, however, agree with
him in his *modus operandi*. The great boulders of sand-
stone, meulière, granite, &c., found in the valley gravel of the
Seine, are attributed by M. Belgrand in the first place to
removal to the line of the Seine valley by diluvial action,
and subsequently to their drifting along the valley channel
by the river action during floods of the Quaternary
period, and he gives some remarkable instances of the
power of water to remove large blocks, and of the rate at
which such blocks move. When, however, it is considered
that the granitic rocks of the Morvan have been trans-
ported some 150 miles, and other rock boulders in propor-
tion, that the angles of many of the large blocks of sand-
stone and of meulière constantly show little wear, and that
they are dispersed irregularly and at various levels, some
imbedded in soft clays, and others in sand or fine gravel
and that these latter are often twisted and contorted, we
can only explain the phenomena by the action of river ice
and transport thereby.

M. Belgrand, on the other hand, shows that a prolonged and steady fall of rain, even if not very heavy, during the winter, now produces great floods—that such rivers as the Yonne and Cure flowing over impermeable strata are subject to sudden and great freshets after a heavy but short fall, whereas the Marne and Seine flowing over permeable strata have their floods retarded, but, at the same time, rendered more permanent by the rainfall having to pass through the strata and delivered in springs. He also shows that when the permeable strata become saturated by long-continued rains, they act as impermeable strata, and that the floods follow close on the rainfall besides being long maintained, so that in the remarkable and long wet winter seasons of 1658 and 1802 the Seine rose at Paris in the one case 29 feet, and in the other 24½ above its ordinary low level, and the floods in the last case lasted three months. M. Belgrand considers that this state of things was a normal condition during the Quaternary period, and he sees reason to believe that the rainfall at that period must have been very much greater than at present.

The ordinary low-water discharge of the Seine at Paris is 75 cubic metres per second; but during these great floods it rose to 2,400 and 2,000 cubic metres. M. Belgrand gives a list of eight such floods in the last two centuries, during which the discharge was above thirty times greater than the ordinary low-water discharge. In rivers flowing over more impermeable strata the difference

is still greater; and he mentions that in the Loire at Orleans it has amounted to as much as 400 times, or 25:10,000. We may take the width of the Seine valley during the high-level gravel period at six kilometres, and during the low-level gravel period at about two kilometres; and M. Belgrand estimates that the river in flood had in the first instance a sectional area of 60,000 square metres, and in the second of 40,000 metres; and, calculating the flow at a given rate per second, the discharge, as compared with that of the present river, would be as under:—

Discharge per second of the Seine at Paris in the present period and during floods in past periods :—

	Extreme rise of river.	Discharge of river.
	Metres	Cubic Metres
Present River . { low water	8·81	75
{ flood-water		2,400
Old River during the { low level stage 20 }		27,000
Quaternary period { high level stage 13 }		to
		60,000

Large as these Quaternary period quantities are, M. Belgrand thinks that there are cases of recent occurrence to prove that it is possible to realise them. He mentions a flood following on a heavy rainfall in the valley of the Armançon, a small river flowing over impermeable strata, with a basin of only 1,490 square kilometres, which had its discharge raised for a short time to 800 cubic metres per second; and he infers that under like conditions of rain and impermeability (by saturation and otherwise) the Seine, with its basin of 78,600 square kilometres, might have its discharge raised to 42,444 cubic metres, showing, that notwithstanding the size of the old river channels, the area drained during a period of greater rainfall would have sufficed for the necessary water supply.

In confirmation of this larger and more permanent supply of water, M. Belgrand instances the presence of the Hippopotamus, the remains of which are found at several places in the Seine basin as well as in that of the Somme, and which would have required for its existence larger and fuller rivers. He also derives a further argument in the presence of this animal, against a prolonged and severe winter cold, which he considers would have been fatal to it. M. Belgrand, nevertheless, argues that the presence of the Reindeer indicates the six summer months' temperature of Scandinavia, not exceeding in the mean 8° centigrade; but with such a summer temperature we hardly see how he can avoid the three months' winter temperature of the same latitude or of 4° 6 per cent. A still more extreme winter temperature is in fact indicated by the presence of the Musk Ox and the Marmot. It is to be observed also that the Reindeer at that time lived as far south as the Pyrenees, and that the physical condition of the drift deposits are, as we have before shown, strictly in accordance with a very low winter temperature. As the Hippopotamus is an extinct species, we do not know how far it may, like the extinct Elephants and Rhinoceroses, have been adapted to live in a severe climate. M. Belgrand's work is full of interesting details of the distribution of these and the other Quaternary animals, not only over the Seine Basin, but in some cases over the whole of France. He gives also

a monograph with figures, by M. Bourguingnat, of all the mollusca of this age found in the Seine Basin. This well-known conchologist makes out that out of a total of 76 there are 38 new species which he considers as extinct, a conclusion which we expect English conchologists will hardly be prepared to agree with, as they have detected no extinct species in these deposits, and find only a few which are not local—a view in which we also believe most French conchologists join. The author considers that the same mammalian fauna is common to both the high-level and the low-level gravels. In one main point, however, do these gravels differ. In those of the high-levels of Montreuil and Bicêtre no Human remains, no Flint Implements, have been found, whereas, in those of the low-levels of Clichy, Grenelle, &c., above 5,000 flints, more or less worked, are stated to have been found by a single collector. Besides these works of early Man, M. Belgrand states that human bones, skulls, and entire skeletons, have been found in these lower gravels; but it seems to us that much of this evidence requires confirmation.

The Quaternary period of the Seine Basin is coeval, in M. Belgrand's opinion, with the Glacial period, and he considers that it was brought suddenly to a close with the low-level gravels. To this Quaternary period the peat deposits immediately succeed, owing, as the author ingeniously suggests, to the suddenly diminished rainfall leaving the rivers clearer and under conditions favourable for the growth of peat, which he shows never takes place in river valleys subject to frequent and heavy floods, but always in valleys where springs abound, and the floods are few and not turbulent.

The latter part of the work is occupied with a minute account of formation of gravel beds, and of the position of the Organic Remains, showing how all the features of those deposits are to be accounted for by ordinary river action, and that the mammalian remains are abundant precisely at those very places where a river with strong currents and numerous eddies would leave them. He endeavours to account also for the fact of all the bones of the larger animals being found in the coarser bottom beds of gravel, by the circumstance that these coarser beds were formed in those deeper water-channels along which only the larger carcases could have floated, and which were afterwards surmounted by those upper beds of sand and finer gravel, which he considers to be due to silting up (*alluvionnement*) of the channel where the river had changed its course to another channel. The brick earth or Loess is ascribed by him, as by English geologists, to river floods. But instead of considering it, as we do, to be produced by successive floods at all the various levels of the river, from the high to the low level, M. Belgrand admits but two levels, the high and the low, and that owing to a sudden elevation of the land, the excavation between these two levels was produced at once without intermediate stages. Consequently, he considers that the height of the Loess above these two levels marks in each case the rise of the flood waters. This, we think, is a weak point in his argument. According to his view, which he illustrates by a section, showing the range of the Loess up the hill slopes, he concludes that the floods of the low-level stage of the river rose, notwithstanding the width of the valley, to a height of 66ft., and during the high-

level stage, to a height of 43ft., which give very much larger sectional areas for the river in flood than is otherwise necessary, and such as we conceive the area drained would have been insufficient to fill even with greatly larger rainfall. For, although the discharge of the Armançon may in a particular case of heavy rainfall have been so large as when multiplied by the whole area to give two-thirds of the required supply, still it is perfectly well known that the discharge by the main river never equals the sum of all its tributaries, and the discharge of the Seine at Paris on that occasion actually only rose to 1,250 cubic metres per second. There are besides beds of gravel on the slopes of Clichy towards Paris, and again on the slopes leading to Charenton distinct beds of gravel at intermediate levels, though of limited extent.

Thus, M. Belgrand ascribes the gravel beds and the Loess of the Seine Basin to old river action, referring the red loam alone of the higher plains above to diluvial causes, in opposition to the view usually received in France, according to which all these Drift beds are divided into the three diluvial deposits of *Diluvium gris*, *Diluvium rouge*, and *Limon* or *Loess*. As we have already expressed very similar views respecting the commonly accepted classification, we cordially agree with the author on this point.

The illustrations forming the second volume constitute a very interesting exhibition of the art of Photo-lithography. The execution varies a good deal, and there are plates which, though valuable for their truthfulness, are rather indistinct. Some of the representations of the Flint Implements are excellent. The work is somewhat large and costly; but as a copious record of facts, an ingenious statement of theory, and a reliable representation of specimens, this work of M. Belgrand will be greatly valued by all those who feel an interest in the remarkable phenomena connected with the present configuration of the country, the distribution of life during the Quaternary period, and especially with the evidence bearing on the Antiquity of Man.

J. P.

OUR BOOK SHELF

The Discovery of a New World of Being. By George Thomson. (Longmans, Green and Co., 1871.)

THE world discovered by this psychological Columbus is the "world of spirits," although he "disclaims all connection with so-called Spiritualists—a sect of modern times," whom he somewhat ungenerously "believes to be either dupes or knaves." Mr. Thomson believes that man consists of two "personalities," an animal personality or body, and a personality he calls spirit, which is the "knowing and conscious we," and which he believes to be as distinct from and as capable of being at almost any moment abstracted from the former as steam is from a steam-engine. Indeed, this latter phenomenon takes place every time the body "goes to sleep," to use the vulgar phrase; for Mr. Thomson believes that the "animal life never sleeps, and cannot sleep, and that to say or think that it, or any other life, can sleep, in the popular sense of the word, is the most glaring absurdity that ever has had possession of the human mind." "What is meant properly by sleep," he goes on to say, "is simply the abstraction or withdrawal of the influence of a being, a spirit, from a being, an animal, the leaving of a servant to itself, from the influence of its lord and master." Mr. Thomson explains the phenomenon of dreaming to be the struggles of this "being, a spirit," to get out of and back into the house of its servant, the body. The frequently

unpleasant consequences of a late supper might have led Mr. Thomson one step further, and suggested to him the probable habitat of the spirit when embodied. How brimful of meaning to Mr. Thomson, then, must be Shakespeare's well-known utterance—"We are such stuff as dreams are made of." The particular merit which he claims for himself as a discoverer is, that he has realised to himself this spirit-world "predicted of old to be in existence," become conscious of himself as a "spirit in the world of spirits," clearly distinct, "in rounded belief," as he puts it, from that other entity, the body; and he declares that any one may make this awful discovery for himself if he only has "faith," shuts himself off from the outer world, and ponders long enough and with sufficient intensity. If our author is really in earnest—and we cannot but think he is—in trying to fathom the mystery of life and of consciousness, we recommend him to approach the subject unprejudicedly from the side of physiology; for so long as a psychologist concerns himself with the phenomena of his "inner consciousness" alone, and neglects the facts of his "outer man," his work is less than half done, and he is as likely to succeed in arriving at the whole truth as Columbus would have been in discovering America, had he contented himself with studying charts and staring longingly across the Atlantic for forty years.

On the Elevation of Mountains by Lateral Pressure; its Cause, and the Amount of it, with a Speculation on the Origin of Volcanic Action. By Rev. O. Fisher, M.A., F.G.S., &c. (From the Trans. of Camb. Phil. Soc. Vol. xi. part iii.)

THIS paper is of considerable interest as bearing upon the question of the internal condition of the earth. Mr. Fisher is of opinion that the elevation of mountain chains and the phenomena of volcanoes can both be accounted for on the hypothesis that the earth is solid. He conceives that "if a sufficient loss of heat has happened since the stratified rocks were formed, to cause a slight diminution in the volume of the earth, then the outer layer will have become too large, and will have had to accommodate itself to the reduced spheroid; and the lateral pressure caused by the resulting failure of support will have given rise to those foldings which have produced mountain ranges;" and an attempt is made by the author to "estimate the lateral pressure which would arise in the outer strata of the earth under such circumstances." Referring to the results obtained by Archdeacon Pratt in India, which seem to show that the density of the earth's crust beneath mountain chains is less than in other places, the author thinks this is only what might have been expected upon the supposition that the elevation of these mountains is due to lateral pressure; for it is evident that the strata would to some extent be supported by the lateral pressure which upheaved them. Here then, he thinks, may be the origin of volcanoes:—"Diminished vertical pressure will enable the interior layers of the crust to pass into a state of fusion, and, "if from an independent cause a partial passage towards the surface is opened for molten rock containing highly heated water, the fluid will convey to a level where the resistance is less the pressure existing at a lower depth, and the force necessary to complete a passage to the surface may be furnished by the pressure of the molten rock and by the steam contained within it." But, although Mr. Fisher believes that the elevation of mountain chains and the phenomena of volcanoes are both of them the result of the same fundamental causes, yet, he thinks, it would certainly be a mistake to regard elevation as the consequence of volcanic action. He does not see how subterranean lakes of molten matter can account for the elongated form which trains of volcanoes like those of the Andes affect; nor how such lakes could have shifted about from one region to another at different geological epochs. His theory, however, offers an explanation of the elongated form

assumed by chains of volcanoes—the shifting of volcanic activity to different regions at successive periods—the spasmodic character of volcanic action, and other volcanic phenomena. J. G.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

The Placental Classification of Mammals

A REMARK made by Prof. Allen Thomson on this subject in a late number of NATURE induces me again to draw attention to some objections I offered to the placental classification in a review of Prof. Rolleston's "Forms of Animal Life" (NATURE, vol. i., p. 81). If this system fails to satisfy so sound a critic and so accomplished an anatomist as Dr. Thomson, there must be some serious deficiencies in it. No doubt De Blainville did good service in calling attention to the wide distinction of Marsupials and of Monotremes from other mammals; but his names, *Omithodelphia* and *Didelphia*, are inappropriate, and even misleading, and the skeletal characters of these two groups furnish quite as important, and far more available, means of diagnosis.

It admits of question whether the divisions of the higher mammals, according to the same system, are the most natural, even if the placenta were the best organ by which to define them. It is true, as Prof. Huxley observes, that the singularities which ally the elephant with the Rodentia have been a matter of common remark since the days of Cuvier, but the placental classification requires us to find still more singular ties between the elephant and the Carnivora. On the other hand the Carnivora lead down by the seals to the true Cetacea, a line of connection broken by the placental arrangement; which is equally opposed to the more doubtful analogy of the whales with the Ruminants. And the third order, with deciduous zonary placentation, the isolated genus *Hyrax*, whatever may be thought of its relations to Rodentia on the one hand and to Ungulata on the other, has at least more likeness to either than to elephants and cats. Again, the different placentation of Elenata may be held only an additional proof of the looseness of an order held together chiefly by negative characters, but if we break it up, shall we obtain a more natural or convenient arrangement by placing the sloths with the Ruminants, *Manis* with Cetacea and Perissodactyla, and *Orycteropus* with Primates?

No doubt embryological characters are justly regarded as the most important for revealing true affinities between animals. But the tenacity of hereditary transmission, which gives them this value, does not appear to belong to placental structure. The placenta is more a maternal than a foetal organ, especially as to its deciduate or non-deciduate character, and should rather rank with organs like the mamma than with the yolk-sac and the amnion.

There are, moreover, many practical objections to the placental classification. The opportunities of obtaining knowledge on the subject are few, the investigation is not always easy, and it cannot be readily verified by subsequent observers.

But the most important objection to De Blainville's system is, that the perishable nature of the structures on which it is based renders it impossible to apply the criterion to fossil animals. It will probably be long before we shall have any notion of what a Sirenian placenta is like; it is only lately that we have learnt what is the real placentation of so common a creature as the rat, but we shall certainly never have the remotest idea of that of a megatherium, a Zeuglodon, or a Rhytina. So that if it be admitted—and surely no one will deny—that any classification of animals which is to be more than a mere aid to the memory, must include all known forms, recent or fossil, it follows that neither placenta, nor brain, nor any other soft part, can be of more than subordinate value in classification. On the other hand, it may be fairly maintained that there is no group of mammals, and scarcely one of the other Vertebrata, of undisputed importance, which cannot be completely defined by the characters of the skeleton.

It is, I venture to think, rather the authority of such illustrious names as Gegenbaur and Huxley than its own merits which have recommended the placental classification of mammals. If we regard the object of classification to be the setting forth of true genetic relationships, all characters must be included, and among

them the placenta has no claim to be a primary index of affinity. And if we only seek for the most practically convenient way of arranging Mammalia, it is to the bones and teeth, rather than to the maternal organs of generation, that we must look.

P. H. PYE-SMITH

Potential Energy

WHILE on the subject of Thomson and Tait's Natural Philosophy, I should like to call attention to the definition of Potential Energy, given in Art. 273, p. 189.

I think it will be found that this definition gives the wrong sign, because the potential energy in any configuration is the amount of work the forces of the system perform in returning to the zero configuration, the ideal position of stable equilibrium.

Thus when a spring is stretched or compressed the potential energy is measured by the kinetic energy which is generated by the work done by the elastic force of the spring by the time the spring has returned to its unstretched condition. With this change of sign the definition now agrees with that given in Art. 484.

Infinite distance being taken as the zero configuration, the potential energy is a positive quantity for such forces as electric and magnetic forces.

With this zero the potential energy for gravitating particles is negative, which is expressed by saying that the exhaustion of potential energy is positive, because as the particles approach their kinetic energy increases, and their potential energy suffers exhaustion and diminishes.

In Art. 485 we read, "The potential at any point, due to any attracting or repelling body or distribution of matter, is the mutual potential energy between it and a unit of matter placed at that point. But in the case of gravitation, to avoid defining the potential as a negative quantity, it is convenient to change the sign. Thus the gravitation potential at any point, due to any mass, is the quantity of work required to remove a unit of matter from that point to an infinite distance."

Although the gravitation potential has had its sign changed, nevertheless the potential at any point *P* for gravitation and for electric and magnetic forces, is defined in the same way as the sum of the quotients of every portion of the mass divided by its distance from *P*.

This is the Potential Function of Green, usually called by the name given by Gauss, the Potential, and is the function which satisfies Laplace's equation.

The gravitation potential is the old force function of Sir W. Hamilton and Jacobi, such that its rate of increase in any direction is the resolved part of the force in that direction on the unit of mass.

The potential, defined as the potential energy in the unit of mass is of opposite sign to the force function; its rate of decrease in any direction is the component force in that direction.

These perplexing changes of sign arise from the fact that in gravitation we have only one kind of matter, the particles of which naturally attract; hence the potential energy is negative, or it diminishes as the particles approach; it is, therefore, convenient to make a change of sign.

In the general case of which electrical and magnetical phenomena may be taken as the type, like particles repel, unlike attract, and the potential energy increases as the particles approach.

These definitions and conventions of signs are, of course, in accordance with those given by Thomson and Tait; the proper signs and names are given also in Briot's "Théorie Mécanique de la Chaleur," but in all the other French books there is great confusion; for instance, in the "Théorie Mécanique de la Chaleur" of Verdet, the potential goes by Green's name, the potential function, but has its sign changed, while the potential energy is called the potential, after Clausius. This also seems to be the nomenclature adopted by the Germans.

It is very necessary that all doubt as to the meaning and value of these important functions should be set at rest; the system adopted in Thomson and Tait's "Natural Philosophy" leaves nothing to be desired.

Development of Barometric Depressions

I LEAVE to those who are equal to it the task of reconciling and discussing "J. K. L.'s" propositions in reference to Indian

meteorology, which appear to be these:—1, "The rainfall in the Himalayas" (instanced by him in proof that rainfall is not the cause of depression), "probably causes a very great depression" (meaning, I now suppose, the great Asiatic depression really due to the rarefaction of the air in Central Asia); 2, "certainly not any currents such as I have described" (viz., currents in accordance with Buys Ballot's Law, having the lowest pressure on their left); 3, "the circuit of the wind in the region of the Himalayas is, so far as we know, in exact accordance with Ballot's Law."

My complaint was that the critic had ignored, not, of course, Part II. of my book, but certain propositions in Part I., as "distinctly enunciated" as those on which he comments, and inseparable from them, though not yet fully discussed.

I will now close, as far as my part is concerned, a discussion, for the opening of which I was responsible, but which has, contrary to my intention, become rather personal than scientific. The question, however, really at issue between us I believe to be one of some interest in meteorology. "Does the fact that precipitation in certain cases, and especially in the warmer regions of the globe, fails to produce baric depression, disprove, or render improbable, the theory (based on substantial evidence) that the depressions which occur in Western Europe are results of precipitation?"

W. CLEMENT LEY

A Safety Lamp

THE article in this week's NATURE on "Foul Air in Mines, and how to live in it" calls to mind a contrivance made use of by the watchmen of Paris in all magazines where explosive or inflammable materials are stored, and suggests the idea that the same may possibly be of service to our miners.

The Paris *Figaro* says, "Take an oblong vial of the whitest and clearest glass, put in it a piece of phosphorus about the size of a pea, upon which pour some olive oil, heated to the boiling point, filling the vial about one-third full, and then seal the vial hermetically. To use it, remove the cork, and allow the air to enter the vial, and then re-cork it. The whole empty space in the bottle will then become luminous, and the light obtained will be equal to that of a lamp. As soon as the light grows weak its power can be increased by opening the vial and allowing a fresh supply of air to enter. Thus prepared the vial may be used for six months."

B. G. JENKINS

Beautiful Meteor

I ENCLOSE a description of meteor, apparently of unusual brilliancy, recently seen by my assistant at Parsonstown, thinking that it may perhaps be interesting to some of your readers.

Carlton Club, London, March 12

ROSSE

"Observed an intensely brilliant meteor. It was first seen in the region about Lepus, whence it moved with a slow and steady motion across the heavens to the S.E. horizon, where it gradually disappeared in a bank of cloud at about 9^h 19^m Greenwich mean time, having occupied seven or eight seconds in moving over 50° of a great circle. The time given may be a few seconds wrong, as it was noted by an ordinary watch. The head was intensely brilliant, of a bluish white colour, and lighted up the whole sky.

"Its brightness was maintained during its entire visibility, and may have been as great as the moon at quadrature. Apparent diameter of the head 42'. It was followed by a very narrow trail about 3' in length and of a reddish hue. It did not leave any phosphorescent train behind it, but at the latter part of its course it threw out some reddish luminous masses, that gradually faded away. Its apparent course was in a great circle through β Canis Majoris to a point near the S.E. horizon, in azimuth S. 25 $^{\circ}$ E., and altitude 81'. For β Canis Majoris the azimuth was S. 20 $^{\circ}$ 52' 4" W., and altitude 16 $^{\circ}$ 43' 3".

"Observatory, Birr Castle, March 8"

WHILE travelling last night, at about twenty minutes to nine o'clock, as we were descending a tolerably high hill, about 5 miles from this city, our road, leading S.S.W., I found myself very favourably circumstanced for seeing a beautiful meteor which was

visible for probably forty seconds. It appeared first as if approaching from the W.S.W. about 40° or 50° above the horizon, unusually large and bright, and leaving a long train of bright spots behind. After a few seconds it seemed extinguished, but in a moment or two flashed out again still brighter, apparently passing due E., at a height of about 25° or 30°, through Eridanus, Lepus, Canis Major, and Argo, and much slower than at first. While passing under Orion two protuberances burst out, giving it the appearance of an arrowhead, or rather a bird flying, as it appeared to have a tail which at the end was a fine smoke colour: it now occupied the space of $1\frac{1}{2}$ ° or 2°. Passing behind a cloud below Regulus it disappeared.

Waterford, March 9

JAMES BUDD

"Whin"

CAN you or any of your readers furnish a probable etymology of the word *whin*? Over all the north of England and south of Scotland basalt is so called. Here we have the *whin-sill* or stratiform basalt—*whin-dykes*, or geological fissures filled with basalt. The vocabularies in treatises on geology give no derivation of this prevalent mining term. In Scotland *whin* seems to typify the hardest mineral known. Burns makes Death say in "Hornbunk," "I might as weel hae tried a quarry o' hard *whin* rock." Surely a satisfactory root for the word in question can be found in Celtic, Old Norse, Danish, or Anglo-Saxon! The Old Norse "fors" is found in the names of several local waterfalls, as for instance "High Force" in Teesdale. At this "force" the river Tees is precipitated over a whin-stone cliff. Soft, high.

WM. R. BELL

Laithkirk Vicarage, Mickleton, March 12

CUCKOO AND PIPIT

SEVERAL well-known naturalists who have seen my sketch from life of the young cuckoo ejecting the young pipit (opposite p. 22 of the little versified tale of which I send a copy)* have expressed a wish that the details of my observations of the scene should be published. I therefore send you the facts, though the sketch itself seems to me to be the only important addition I have made to the admirably accurate description given by Dr. Jenner in his letter to John Hunter, which is printed in the "Philosophical Transactions" for 1788 (vol. lxxviii., pp. 225, 226), and which I have read with pleasure since putting down my own notes.

The nest which we watched last June, after finding the cuckoo's egg in it, was that of the common meadow pipit (Tidlar, Mosscheeper), and had two pipit's eggs besides that of the cuckoo. It was below a heather bush, on the declivity of a low abrupt bank on a Highland hill-side in Moidart.

At one visit the pipits were found to be hatched, but not the cuckoo. At the next visit, which was after an interval of forty-eight hours, we found the young cuckoo alone in the nest, and both the young pipits lying down the bank, about ten inches from the margin of the nest, but quite lively after being warmed in the hand. They were replaced in the nest beside the cuckoo, which struggled about till it got its back under one of them, when it climbed backwards directly up the open side of the nest, and hitched the pipit from its back on to the edge. It then stood quite upright on its legs, which were straddled wide apart, with the claws firmly fixed half-way down the inside of the nest among the interlacing fibres of which the nest was woven; and, stretching its wings apart and backwards, it elbowed the pipit fairly over the margin so far that its struggles took it down the bank instead of back into the nest.

After this the cuckoo stood a minute or two, feeling back with its wings, as if to make sure that the pipit was

fairly overboard, and then subsided into the bottom of the nest.

As it was getting late, and the cuckoo did not immediately set to work on the other nestling, I replaced the ejected one, and went home. On returning next day, both nestlings were found, dead and cold, out of the nest. I replaced one of them, but the cuckoo made no effort to get under and eject it, but settled itself contentedly on the top of it. All this I find accords accurately with Jenner's description of what he saw. But what struck me most was this: The cuckoo was perfectly naked, without a vestige of a feather or even a hint of future feathers; its eyes were not yet opened, and its neck seemed too weak to support the weight of its head. The pipits had well-developed quills on the wings and back, and had bright eyes, partially open; yet they seemed quite helpless under the manipulations of the cuckoo, which looked a much less developed creature. The cuckoo's legs, however, seemed very muscular, and it appeared to feel about with its wings, which were absolutely featherless, as with hands, the "spurious wing" (unusually large in proportion) looking like a spread-out thumb. The most singular thing of all was the direct purpose with which the blind little monster made for the open side of the nest, the only part where it could throw its burthen down the bank. I think all the spectators felt the sort of horror and awe at the apparent inadequacy of the creature's intelligence to its acts that one might have felt at seeing a toothless hag raise a ghost by an incantation. It was horribly "uncanny" and "grewsome."

J. B.

The University, Glasgow

DR. G. E. DAY

IN a former number, under the date of February 8, we had the painful duty of announcing the death, at the age of fifty-six, of Dr. George Edward Day, F.R.S., Emeritus Chandos Professor of Medicine in the University of St. Andrews, which took place at Torquay on January 31, 1872. Most of his earlier friends had probably heard of the sad accident which reduced him to a state of bodily helplessness, and which darkened his latter years; but few of those who remembered him only as the genial witty Cantab, overflowing with life and spirits, and as the brilliant medical student at Edinburgh, carrying everything before him in class-room and debating hall, or later, as the active untiring President of the Medical Examinations at St. Andrews, would have supposed him capable of the cheerful resignation with which he submitted to his enforced exclusion from all participation in active, professional, and social life.

The story of Dr. Day's life is a sad record of brilliant expectations suddenly wrecked, and long continued struggles against irreparable calamities.

As the eldest son of a wealthy country gentleman of good position, his fortune seemed assured from his birth; but the failure of the Swansea Bank in 1825, when he was scarcely ten years old, ruined his father, and led to his removal to the house of a widowed grandmother.

In 1834, after some preparation under a private tutor, he went up to Cambridge with the reputation of an able mathematician, and a good classical scholar. At the University he worked splendidly by fits and starts, but the period between 1834 and 1837 does not belong to the working era of Cambridge, and George Day's natural love of fun and the fascination of his manner combined to render his society especially attractive to his comrades, and the result was, that he came out as low as twelfth among the wranglers of his year.

On leaving Cambridge he resolved to adopt medicine as his future profession, and went to Edinburgh, where he at once took his place among that brilliant band of

* "The Pipits," illustrated by Mrs. Hugh Blackburn (Glasgow: Maclehose, 1872).

young men who reckoned John Goodsir, Edward Forbes, and many others of similar promise amongst their ranks. On leaving Edinburgh he at once came to London, and taking a house at the West End, attempted to establish himself as a pure physician. During these eight or nine years of his London life, Dr. Day laboured on with unwearied industry and patience, lecturing at the Middlesex and other metropolitan medical schools, writing for reviews, translating from German, and turning his versatile talents and his special knowledge of physiological chemistry to account in every way. The result of this heavy strain was a threatening of brain disease, which, according to the verdict of his medical advisers, could only be warded off by complete rest and cessation from the cares in which he was immersed.

At that moment the death of an old friend, Dr. John Reid, opened the prospect to him of obtaining the Chair of Medicine at St. Andrews. His success in this probably saved his life, for the removal from the turmoil of a struggling London career to the comparative ease of the Scottish University arrested the threatenings of disease, and enabled him to recover some of his old vigorous tone. During the 13 years that Dr. Day held the Chair of Medicine at St. Andrews, from 1850 to 1863, he made it his special duty to promote the honour and further the interests of the University by raising the character of medical degrees; and so successfully did he accomplish this task, that the discredit which had belonged in former days to the M.D. degree of St. Andrews was completely effaced under his presidency of the Examining Board. A new system of stringent *viva voce* and written examinations was then inaugurated, which justified those who graduated in his time in regarding their attainment of the M.D. degree of St. Andrews as a professional honour of which any man might be proud.

In 1857 Dr. Day's prospects of a more prosperous future than he had as yet been able to look forward to were completely destroyed by the accident to which we have already referred, and which befell him in the course of a vacation tour in the English Lake District. On a bright morning at the end of the August of that year, he had set forth from his hotel at Patterdale in full vigour and strength, bent on "learning a new wrinkle about Helvellyn," as he himself expressed it, by making his way to the summit along a recently opened path. He made the ascent as he had designed, but instead of returning by the same track, he struck off in the direction of the white lead mines; and while walking along what he mistook for a miner's path, the ground gave way under him, and he fell into what proved to be a horizontal chimney or culvert, constructed to carry off the sulphurous, arsenical, and other gases, whose deposits had proved injurious to the sheep grazing on the hill side. He was rescued after three hours of anxious suspense, but the proximate results of that accident were dislocation of the right elbow and two fractures of the same arm, the upper one in the surgical neck of the bone of the humerus, which never united. The subsequent effects were the complete destruction of his general health, which obliged him in 1863 to give up the Chair of Medicine at St. Andrews and retire from active life. A removal to the milder climate of Torquay had little effect in arresting the train of symptoms which year by year marked the progress of disease, and were, it is conjectured, the result of a jar to the spine sustained by his accident on Helvellyn, which had, in truth, proved to him the beginning of the end.

And such was the checkered career of this man of brilliant promise, unflinching bravery of spirit, clear judgment, and tender heart. Disappointed again and again, he always met his troubles manfully, and turned them to good account for himself or others. We have given no list of the various honours which he attained in his profession, or of his literary works, for the detailed reports of these particulars are contained in the various obituary

notices which have appeared of Dr. Day in the medical and other journals, to whose pages, as well as to our own, he was a frequent contributor.

OCEAN CURRENTS

A NEW interest seems now to be taken in Ocean Currents, and much is being said and written upon the subject. In the investigation of this subject it is very important that we should understand well all the forces and agencies concerned in the production and maintenance of the currents, and that we should consider well all the principles, and theories based upon hypothetical forces, which have come down to us from preceding generations, however plausible and however much sanctioned by high authority they appear to be. As in the case of the winds, so also in ocean currents, the modifying force arising from the earth's rotation has a very important bearing, and should be well understood. There are certain erroneous views in connection with this force, which have come down to us from preceding generations, and which are contained in text-books, and are being taught in colleges and schools, which are liable to have, and do have, a mischievous bearing upon this subject. These are the more dangerous because they appear to have received at least the tacit sanction of past ages, so that almost any one is liable to adopt them without much consideration. Prof. Colding has in this way been unsuspectingly let into error in his recent paper on ocean currents. We are all familiar with the usual explanation of the trade-winds contained in text-books, which assuming that a particle of air at the equator, at rest relatively to the earth, and consequently having a lineal velocity in space of about 1,000 miles per hour, is forced to move toward the pole, it will, on arriving at the parallel of latitude where the earth's surface has a velocity of only 900 miles, still have its velocity of 1,000 miles per hour in the case of no friction, and consequently have a relative velocity of 100 miles per hour, and on arriving at the parallel of 60°, will still have its initial velocity of 1,000 miles, and consequently have a relative velocity of 500 miles per hour. But this is at variance with a fundamental and well-established principle in mechanics. The force in this case is a central force, or at least the compound perpendicular to the earth's axis can be neglected, since it can have nothing to do with any east or west motion. This being the case, the principle of the preservation of areas must be satisfied, and consequently the particle of air, when it arrives at the parallel where the earth's surface has a velocity of 900 miles, must have a velocity of more than 1,000 miles, and a relative velocity of more than 200 miles per hour, and on arriving at the parallel of 60°, where the earth's surface has a velocity of 500 miles, it must have a velocity of 2,000 miles, and consequently a relative velocity of 1,500 miles, instead of 500 miles per hour. Adopting thoughtlessly, and very naturally, the erroneous principle which is usually taught, that a particle of air or of water in moving toward or from the pole, tends to keep its initial lineal velocity relative to space, Prof. Colding estimates the amount of deflecting force due to the earth's rotation, eastward when the particle is moving towards the pole, and westward when moving from the pole, and the result is, that his force is just one half of what it really is. Consequently, all the results based upon his estimated amount of this force should be doubled. Prof. Colding has also entirely neglected one component of the force due to the earth's rotation. It has been shown by Prof. Everett, and also by the writer, that when a body moves east or west, there is also a similar deflecting force due to the earth's rotation, exactly equal to the former. Prof. Colding has, therefore, taken into account only the one-fourth part of the whole force. If he had taken in this latter component of the force also, and resolved it in the direction of the line of motion and perpen-

dicular to it, as he did the former, he would have found that the parts in the direction of motion, arising from both components, exactly cancel one another in all cases, and that the resultant of both components is a force perpendicular to the direction of motion. This force then tends only to change the direction of the motion, and never to accelerate or retard it, in whatever direction it may be. Prof. Colding's result, therefore, that the velocity of the current is accelerated by the earth's rotation, when moving in certain directions, and retarded in others, is erroneous.

It is known that there are two theories with regard to the cause of Ocean Currents: the one, that they are caused by the winds acting upon the ocean, the other, advocated by Dr. Carpenter, that they are caused by a difference of density of the ocean between the equator and the poles, due to a difference of temperature. The tendency of both theories is in the same direction, and the currents, no doubt, are in some measure due to the forces belonging to each theory. The history of the former theory, and the high authority which can be appealed to in its support, are well known, but we have reason to think that the forces, and the effects of them, in the former theory, are quite subordinate to those of the latter. The well-known explanation of the Gulf Stream by the former theory assumes that there is a heaping up of the water of the ocean in the Gulf of Mexico by the action of the trade winds, sufficient to change the sea-level enough to cause the observed current passing through the Strait of Florida. But the trade winds cannot have much effect in causing a heaping up of the water on the coast of Mexico, since the force is applied to the surface merely, and tends to produce only a surface current, while all the great body of the water, except a little of the surface, is free to flow back. It is true there must be a slight change of sea-level to give rise to a force sufficient to overcome the resistances to this under tow, but these are extremely small since the velocity of this under tow, including all the great depth of the ocean, except the superficial westward current, is very small. That the merely superficial part of the equatorial current is mostly caused by the trade-winds may be true, but the Gulf Stream, which is not directly acted upon, except by the very gentle south-west winds, and which is not merely a surface-current, must be mostly accounted for by the other theory. Let us now see what can be learned upon this subject from observation. Instances of a great change of water-level in shallow canals have been cited to show the influence of the wind in causing a heaping up of the water at the one end; but the water in these cases being very shallow, the force may be regarded as applied somewhat to the whole body of the water, and the under counter-current is thus prevented, but the case is very different in a deep ocean. It is well known from the discussion of tidal observations that the influence of the wind in changing the sea-level is very small. If the force of the trade winds causes a higher sea-level in the Gulf of Mexico, we know that the west winds in higher latitudes must cause a similar rise of sea-level on the west coast of Europe, for the sum of the moments with reference to the earth's axis, of the forces, west between the tropics and east in higher latitudes, must exactly balance each other. If the explanation of the Gulf Stream requires that the level of the Gulf of Mexico should be raised about twelve feet, as shown by Prof. Colding, then there must be about an equal change of level on the west coast of Europe, if these changes are caused by the winds; for although the extent of coast receiving the west winds may be greater than that receiving the east winds, yet this is counter-balanced by the circumstance that the force of the west winds acts at a less distance from the earth's axis, which requires that they should be stronger. If, then, the west winds cause a change of sea-level on the coast of Europe, say of ten feet, then any change in the force of these

winds at different seasons must cause a very perceptible change of sea-level. Now, we know that the force of the west wind on the Atlantic Ocean is considerably greater in the spring than the autumn. There should therefore be a corresponding difference in the mean level of the sea, and this mean level on the coast of Europe should be greatest in the spring. But the discussion of the tidal observations made at Brest, shows that the mean level of the sea, after being corrected for the barometer and a very small astronomical term affecting the mean level, is about four inches lower in the spring when the winds are strongest than in the autumn when they are weakest. (Proceedings of the American Academy of Sciences and Arts, vol. vii. p. 32.) The discussion, likewise, of the tides of Boston Harbour gives a similar result, except that the range of the monthly means is still less, being less than three inches. (U.S. Coast Survey Report for 1868.) These results should receive the attention of those who maintain that great changes of sea-level are caused by the winds.

In a paper by the writer, published in *Silliman's Journal* (second series, vol. xxxi. p. 45) there are several pages given to the subject of ocean currents, in which it is maintained that the principal agency in their production is difference of temperature of the sea-water between the equator and the poles. The principal effects of the earth's rotation are there given, which are too numerous to be recited here. In addition to the results there given, the following additional thought may be given here as being perhaps new. As the surface-water flows toward the poles the deflecting force of the earth's rotation presses it toward the east. In like manner as the water below flows toward the equator, there is a similar force pressing it toward the west. These forces are small, but they must nevertheless cause a gradual rising of the cold water at the bottom on the American coast, and this, perhaps more than the Greenland current, causes cold water there. The Gulf Stream of warmer water cuts its way through this cold water gradually rising from the bottom, and hence the cold walls observed by the U.S. Coast Survey.

Mr. Croll seems committed to the wind theory, and is unwilling to admit that the theory advocated by Dr. Carpenter can have even a subordinate effect. His principal argument is based upon an experiment of M. Dubuat. I know not under what circumstances this experiment was made, but of course it was with a comparatively shallow canal or stratum of water, and the result is no doubt correct for the depth of water with which the experiment was made. A much less force on each particle of a large body of water is sufficient to overcome the cohesion of the particles, and produce motion than upon a small one, just as a small drop of water remains suspended to a twig, while the same force of gravity causes a large one to drop off. The case therefore of the ocean is very different from that of a shallow canal. As Mr. Croll insists that Dr. Carpenter's experiment, to be applicable to the case, should have been made with a canal 120 feet long, and only one inch deep; so it might be insisted that M. Dubuat's experiment, to be applicable to Mr. Croll's case, should be made with a canal or body of water three or four miles deep. But there is no necessity for us to make any such experiments, for nature is performing the experiment regularly every six hours, and all that we have to do is to observe. The attraction of the moon changes the level due to the attraction of the earth alone, and puts the ocean, as it were, upon an inclined plane with a gradient of about two feet in the distance of a quadrant, and the water slides down, causing a rising of the tide at one place and a falling at another; and in six hours this gradient is reversed, and the reverse motion of the water follows, thus causing the regular ebbing and flowing of the tides. If M. Dubuat's experiment were applicable to the ocean, the moon could not cause a tide at all unless its mass were about fifteen times greater.

Cambridge, Mass., U.S.A.

W. FERREL

FERGUSSON'S RUDE STONE MONUMENTS*

IN Mr. Fergusson's "Handbook of Architecture," published in 1854, one chapter of about fifty pages is de-

voted to Megalithic, or, as he prefers to call them, Rude Stone, Monuments. Ever since that period he has been collecting materials on this interesting subject, and the result is now before us, in the work which forms the subject

FIG. 1.—Dolmen at Castle Wellan, Ireland. From a drawing by Sir Henry James.

of this notice. In it he confines himself to the classes of monuments indicated in the title, omitting all reference to hut circles, Pict's houses, brochs, and other buildings

composed of smaller stones; not because he doubts that they belong to the same period, "but because their age being doubtful also" it would only complicate the

FIG. 2.—Dolmen de Bousquet. From a drawing by E. Cartailhac.

argument to introduce them. He limits himself therefore to tumuli, menhirs or stone pillars, stone circles, avenues, and dolmens. All these we find sometimes singly, some-

times in combination, the tumulus containing a dolmen, being surrounded by one or more stone circles, and surmounted by a menhir. Fig. liii., representing the celebrated

FIG. 3.—Nine Ladies, Stanton Moor. From a drawing by L. Jewitt.

tumulus of New Grange, near Drogheda, gives a good idea of the large barrows; it was originally surrounded by a circle of stones, most of which, however, have disap-

peared. Fig. 3 represents the stone circle, known as the Nine Ladies at Stanton Moor.

The typical "Dolmen" may be described as a massive

FIG. 4.—Long Barrow, Kennet, restored by Dr. Thurnam. *Archæologia*, xii.

stone resting on three supports; the celebrated Kits Coty House, near Maidstone, may be regarded as a typical ex-

* "Rude Stone Monuments." By James Fergusson, D.C.L., F.R.S. (London: John Murray, 1872.)

ample. Fig. cvii. represents one at Halskov, in Denmark, raised on a small mound, and surrounded by a circle of stone. Fig. I, representing a Dolmen at Castle Wellan, Ireland, and Fig. 6, one at Grandmont, in Bas Languedoc, are more ex-

ceptional types. Dolmens are sometimes covered by a mound of earth (like the Gib Hill example, excavated by Mr. Bateman), sometimes free, as in the preceding figures. That all the earlier ones were covered, says Mr. Fergusson, "is more than probable, and it may since have been originally intended to cover up many of those which

now stand free; but it seems impossible to believe that the bulk of those we now see were ever hidden by any earthen covering."

The tumuli which contain megalithic chambers closely resemble the dwellings even now used by many northern nations, the Siberian Yurt, for instance, consists of a central

FIG. 5.—View of Interior of Chamber at Uby. From Madsen.

chamber, generally sunk a little below the surface, built of stones or timber, and heaped over with earth, so as to form a mound. The Tchutski huts are very similar. "They are," says Captain Cook, "sunk a little below the surface of the earth. One of them which I examined

was of an oval form, about twenty feet long and twelve or more high. The framing was composed of wood and the ribs of whales, disposed in a judicious manner, and bound together with smaller materials of the same sort. Over this framing is laid a covering of strong coarse

FIG. 6.—Dolmen of Grandmont.

grass, and that, again, is covered with earth, so that, on the outside, the house looks like a hillock supported by a wall of stone three or four feet high, which is built round the two sides and one end."

The huts of the Esquimaux and Lapps are built on the same model, and have generally a longer or shorter

covered passage leading to the door, the object of which is to keep the cold out of the central chamber. Round the walls of the latter are ranged seats for the inmates, and part of the space is often separated off by partitions. So closely do many of our Northern tumuli correspond to these descriptions, that Nilsson long ago

suggested many of them having been originally used as dwelling places, and converted subsequently into tombs. Fig. xi., for instance, represents the chamber of a tumulus near St. Helier, in Jersey. Here we have the central room, with partitions, and the passage leading to the door. In some few cases the dead have been found sitting round the sepulchral chamber, with their arms and implements by their side, just as they may be supposed to have sat during life. Fig. 5 represents the chamber of a tumulus at Uby in Denmark. Stonehenge itself (Fig. 8) seems to be constructed on the same model: the mound, however, being absent, or only represented by the encircling ring of earth.

In determining the date of particular tumuli, Mr. Fergusson seems to me to attach too much importance to objects found on, or near the surface, and which often have no doubt been accidentally dropped, or belong to secondary interments. Thus he refers to the two objects of iron found at Gib Hill, as if they justified us in ascribing that interesting tumulus to the iron age. But Mr. Bateman, by whom that mound was opened, expressly states that the objects of iron were not found in the central cist, but they belonged to a secondary interment. They throw, therefore, no more light on the date of Gib Hill itself than the fragments of ginger-beer bottles which abound

in the area of Stonehenge do on the period to which it belongs. This is a consideration which is of great importance; because the history of these megalithic monuments, the race by whom, and the date at which they were constructed, are most interesting questions of archaeology. Although few now regard Stonehenge as a Druidical temple, still archaeologists are almost unanimous in regarding it as very ancient; while the class of megalithic monuments they consider to have begun in pre-historic times, and to have continued in out-of-the-way parts down to a comparatively recent period. Mr. Fergusson, on the contrary, is of a different opinion. He endeavours to show that these monuments belong to one period, and to comparatively recent times:—

"However this may be," he says, "I trust that this work may lay claim to being, in one respect at least, a contribution to the cause of truth regarding the much-disputed age and use of these rude stone monuments. It states distinctly, and without reserve, one view of the mooted question, and so openly, that any one who knows better can at once pull away the prop from my house of cards and level it with the ground. If one thing comes out more clearly than another in the course of this investigation, it is that the style of architecture to which these monuments belong is a style, like Gothic, Grecian, Egypt-

Fig. 7.—Dolmen at Puliccondah.

tian, Buddhist, or any other. It has a beginning, and middle, and an end; and though we cannot yet make out the sequence in all its details, this at least seems clear—that there is no great hiatus; nor is it that one part is pre-historic, while the other belongs to historic times. All belong to the one epoch or the other. Either it is that Stonehenge and Avebury, and all such, are the temples of a race so ancient as to be beyond the ken of mortal men, or they are the sepulchral monument of a people who lived so nearly within the limits of the true historic times that their story can easily be recovered."

As already mentioned, the latter is Mr. Fergusson's view. Almost alone among English archaeologists, he considers that Stonehenge is part Roman, and believes it to have been erected by Ambrosius, between the years 466 and 470 A.D., in memory of the British chiefs treacherously slain a few years previously. This theory I have discussed in "Pre-historic Times," and, as I have little to alter in, or add to, what is there said, I will not here repeat my arguments.

As regards Abury, the second in importance—if, indeed, it be the second and not the first of these monuments

Mr. Fergusson says:—"I feel no doubt that it will come eventually to be acknowledged that those who fell in Arthur's twelfth and greatest battle were buried in the ring at Avebury, and that those who survived raised these

stones and the mound at Silbury, in the vain hope that they would convey to their latest posterity the memory of their prowess" (p. 89). In fact, Mr. Fergusson refers to this period all the similar monuments in England, a conclusion which seems to me in itself most improbable, and which becomes still more so if we consider the similar remains of other countries. The Irish examples he considers to be somewhat earlier; the Moytura remains, for instance, being perhaps as early as the first century B.C. As regards the North, he regards the celebrated tumulus of Maes Howe as probably the "tomb of Havard, or of some other of the Pagan Norwegian Jarls of Orkney;" while the Stones of Stennis can hardly, he thinks, "be carried back beyond the year 800," to which period he refers all the megalithic remains in those islands. In short he regards these monuments, whether in Britain, Scandinavia, Germany, France, Spain, Algeria, or India, as post-Christian in date, and in many cases not more than a few hundred years old. Such a conclusion seems to me entirely inconsistent with architectural history. Thus in more than one case we know of early churches, probably belonging to the 10th or 11th centuries, which are constructed over dolmens.

Mr. Fergusson admits that the great tumulus near Sardis (Fig. 1, p. 31) is rightly identified as the tomb of Alyattes, was erected in the sixth century, B.C., and was

described by Herodotus; that some of the tumuli on the eastern shores of the Mediterranean are certainly "as old as the thirteenth century, B.C.": that the practice of burying in tumuli must have existed for many centuries before such tombs could have been constructed; and that the age in which they "were erected was essentially the age of bronze: not only are the ornaments and furniture found in the Etruscan tombs generally of that metal, but the tombs at Mycenæ and Orchomenos were wholly lined with it;" a fact which is the more interesting when we remember that all the metallic objects found in the tumuli round Stonehenge were of bronze.

Again, let us consider the class of monuments which consist of a free dolmen standing on a mound, and surrounded by one or more stone circles. This type is very widely distributed. A Danish example has already been given, Fig. 5. Fig. 4 represents the long barrow at Kennet, near Marlborough, after Dr. Thurman; Fig. 2 is the Dolmen de Bousquet in the Aveyron; lastly, Fig. 7 is a similar monument at Pullicondra, near Madras. These tumuli, though differing in detail, are identical in all essential

archæologists, that our megalithic monuments belong to very different periods and people, and *not* all to one race or one epoch.

I cannot now enter into the consideration of the dates to which Mr. Fergusson ascribes individual monuments; I doubt whether any belong to so recent a period as he supposes: and can only express my surprise at the certainty and confidence which he feels in his own opinions—a certainty sometimes, however, oddly expressed, as, for instance, when he tells us, speaking of the crosses at Katakpur, which he considers to be Christian and contemporaneous with a group of neighbouring dolmens, that "their juxtaposition and whole appearance render escape from this conclusion apparently inevitable."

But while I cannot accept Mr. Fergusson's peculiar theories, I cannot conclude without thanking him for the labour and care with which he has brought together a great number of illustrations, and a vast mass of facts, on this most interesting subject. In a review, one naturally dwells on points of difference, but every one must accord to Mr. Fergusson the credit which, in the following passage from his preface, he claims for himself; though I would venture to add that the unintentional self-criticism in the latter sentence seems to me not inapplicable. "I have," he says, "spared no pains in investigating the materials placed at my disposal, and no haste in forming my conclusions." His conclusions are, I think, in some cases, hasty and untenable; some seem inconsistent with one another; but no one can deny to his work the merit of being a rich and trustworthy storehouse of facts.

JOHN LUBBOCK

THE STUDY AND TEACHING OF MECHANICS

A LECTURE on this subject, being one of the series of lectures at the College of Preceptors on the Teaching of Physical Science, was given by Prof. W. G. Adams, of which the following is the substance:—

Mechanics treats of the laws of equilibrium and of motion of bodies, and in its widest sense, as the science of energy, must include all branches of Physics, for the solid, liquid, and gaseous states of bodies are determined by the more or less free motion of their molecules, and heat, light, electricity and magnetism are all different forms of motion. The study of the laws of equilibrium and of visible motion is important, both for their practical applications and because on them are founded the principles of thermo- and electro-dynamics. Before entering on a study of mechanics, students should have a knowledge of algebra and geometry, and on account of the importance of accurate measurement, the elements of trigonometry should also be studied. By a proper method of teaching geometry, boys can be taught to think, and the exact definitions and proofs of Euclid's Elements are better fitted to train the judgment and the reasoning powers than any less exact system of geometry. The way to teach geometry (and the same remark applies to mechanics) is not to expect boys to get up their Euclid from a book, and to say it off by the aid of a book of figures (a system which has been practised in many schools), but to explain the meaning of and illustrate every proposition, so that boys may understand it. The true method of teaching mechanics is illustrated by the way in which Galileo established the first principles of dynamics, and placed them before his pupils. Due weight should be given both to experimental and to rational mechanics, and the best way of bringing the subject before students is to have parallel but distinct courses of experimental and theoretical lectures attended by students at the same time. The practical applications of the subject are important, and some of them of great simplicity. The "Triangle of Forces" may be employed to build up diagrams to represent the thrusts on a jointed

FIG. 8.—General Plan of Stonehenge, from Knight's "Old England."

points. If these monuments all belong to post-Christian times, they must have been erected by very different races of men. Mr. Fergusson, indeed, admits that they are the work of very different races; how then does he account for the remarkable similarity existing between them? He denies that the Celts, Scandinavians, or Iberians were themselves naturally "rude stone builders," and endeavours to remove the difficulty by an explanation which is most important, because it seems to me to involve the practical abandonment of the conclusion, which, as he told us in the preface, is the central feature of his work. This style of art, he says, "seems to have been invented by some pre-Celtic people, but to have been adopted by Celts, by Scandinavians, by British, and Iberian races."

But if Europe was once occupied by a pre-Celtic, megalithic-monument-building race, surely some of our megalithic monuments must be ascribable to that time and race, and we come back therefore to the general opinion of

framework; so that by "Diagrams of Forces" the conditions of stability of loaded structures, and the form and tensions of suspension bridges, could at once be determined, by measurement of these diagrams or by calculation from them. Of the variety of text-books on the subject of mechanics, the teacher should reject books that profess to be adapted for examinations, as well as those which contain gross errors on the laws of friction, or on the inertia of matter and the laws of motion, or on the subject of dynamical units and should select from those which are not liable to such objections.

Competitive examinations may be useful if they are made tests of thorough knowledge; but too often they injure the student who is preparing for them by narrowing his mind, and create a class of dabblers in science, and are worthless for the purpose for which they are intended. Test examinations given to a class on the subject of their lectures are the best tests of the knowledge and progress of the student.

In teaching the laws of equilibrium of liquids and of gases, the same method must be followed as in teaching the laws of equilibrium and of motion of solids; and in addition to lectures and ordinary teaching students should have the opportunity of making experiments and measurements in these subjects in a physical laboratory. Some knowledge of other kindred sciences is necessary before a student can be said to have an intelligent knowledge of the principles of mechanical science. Accurate investigation and experiment show that near the melting and the boiling points the special properties and laws of solids or of liquids are no longer true, and Dr. Andrews has pointed out the existence of a border-land between the liquid and the gaseous states, and has shown that there is no breach of continuity between them. Taking a model, of which three rectangular edges shall represent the pressure, volume, and temperature, the upper surface will represent the state of the substance, and will explain in what way it is possible to pass from the liquid to the gas without change of state or any sudden change of volume. The ease with which we can conceive of the state of a gas under different circumstances, when we have such a model before us, shows the importance of employing figures and models to give a boy clear ideas of the propositions of mechanics.

Regarding Mechanics in its wider sense as the Science of Energy, there are three great principles—the Conservation, the Transformation, and the Dissipation of Energy, which have been established, and these principles are illustrated in the conversion of water into steam, in winding up a watch, in the diffusion of gases, in the conduction of heat, in the friction of the tides on the earth, and in the rushing of water down a mountain side. This latter source of energy has been employed in piercing the Mont Cenis tunnel.

The accuracy of the calculations by which the axes of the two tunnels on opposite sides agreed so completely with one another shows the importance of accurate measurement, and of the correct application of theoretical principles to practice.

These principles of energy tell us that in raising the waters of the ocean to the mountain tops, as much energy must be expended as can be expended by those waters in their return to the ocean, and the atmosphere, acted upon by the solar heat, is the vast air-engine by which these changes are accomplished.

NOTES

At the last meeting of the Royal Society the names of the candidates for election into the Society were read, in accordance with the statutes, as follows:—Andrew Leith Adams, Surgeon-Major; William Grylls Adams, M.A.; William Aitken, M.D.; Alexander Armstrong, K.C.B., M.D.; Edward Middleton

Barry, R.A.; John Beddoe, B.A., M.D.; Henry Bowman Brady, F.L.S.; Frederick Joseph Bramwell, C.E.; James Brunlees, C.E.; Edwin Kilwick Calver, Capt. R.N.; Alexander Carte, M.A., M.D.; William Chinnio, Commander R.N.; Prof. Arthur Herbert Church, M.A.; Fredk. Le Gros Clark, M.R.C.S.; Prof. John Cleland, M.D.; Herbert Davies, M.D.; Henry Dircks, F.C.S.; August Dupré, Ph.D.; Michael Foster, jun., M.A., M.D.; Peter Le Neve Foster, M.A.; Wilson Fox, M.D.; Arthur Gamage, M.D.; Prof. Thomas Minchin Goodeve, M.A.; Townshend M. Hall, F.G.S.; Edmund Thomas Higgins, M.R.C.S.; Rev. Thomas Hincks, B.A.; Rev. A. Hume, LL.D.; Henry Hyde, Lieut.-Col. R.E.; Prof. William Stanley Jevons, M.A.; Edmund Charles Johnson, F.R.G.S.; George Johnson, M.D.; Prof. Thomas Rupert Jones; John Leckenby, F.G.S.; Clements R. Markham, Sec. Geog. Soc.; William Mayes, Staff-Comm. R.N.; Edmund James Mills, D.Sc.; Thomas George Montgomerie, Major R.E.; Robert Stirling Newall, F.R.A.S.; Edward Latham Ormerod, M.D.; Francis Polkinghorne Pascoe, F.L.S.; Prof. Oliver Pemberton; Rev. Stephen Joseph Perry; John Arthur Phillips, F.C.S.; Bedford Clapperton T. Pim, Captain R.N.; William Overend Priestley, M.D.; Charles Bland Radcliffe, M.D.; Edward John Routh, M.A.; George West Royston-Pigott, M.D.; William Westcott Rundell; William James Russell, Ph.D.; Osbert Salvin, M.A.; Harry Govier Seeley, F.L.S.; Alfred R. C. Selwyn (Geol. Survey, Canada); Peter Squire, F.L.S.; George James Symons, V.P. Met. Soc.; Edwin T. Truman, M.R.C.S.; Wildman Whitehouse, C.E.; Henry Woodward, F.G.S.; Archibald Henry Plantagenet Stuart Wortley, Lieut.-Col.

THE EARL OF LONSDALE, whose death is recorded this week, was the father of the Royal Society, his election having taken place sixty-two years ago, in 1810. This honour now devolves on Sir Henry Holland, elected in 1815.

THE death is announced, on the 3rd inst., of Dr. A. B. Granville, F.R.S., at the age of 88. He was one of the oldest Fellows of the Royal Society, having been elected in 1817, and was member of a large number of foreign learned societies.

WE are very glad to be able to state that intelligence has just been received from Prof. Huxley that his health has already been greatly renovated by the pure air of Upper Egypt. He wrote from Thebes, and was then contemplating a visit to Assouan, from which he would probably have returned to Thebes before this.

SIR WILLIAM THOMSON has accepted the office of President of the Geological Society of Glasgow.

THE Radcliffe Travelling Fellowship at Oxford has been awarded to Mr. F. H. Champneys, B.A. of Brasenose College. This Fellowship is of the annual value of 200*l.*, and tenable for three years, provided the Fellow does not spend more than eighteen months within the United Kingdom.

THE President of the Quekett Microscopical Club will hold a *soirée*, on Friday evening, March 15, at University College.

DR. LIEBREICH, the eminent ophthalmist, of St. Thomas's Hospital, delivered a lecture at the Royal Institution on Friday evening last, on certain faults of vision, with special reference to Turner and Mulready. The later "aberrations" of Turner's style he attributed to a physical change in the refractive power of the eye, by which illuminated points were converted into illuminated lines. The change of manner in Mulready's later pictures he accounted for, in like manner, by increasing yellow degeneration of the crystalline lens. We hope in a future number to give a report of the lecture.

THE Royal Academy of Sciences of Belgium offers prizes on the following subjects for Essays to be sent in during the year 1873:—(1) A simplification of the theory of the integration of equations of the two first orders; (2) On the disturbing causes which influence the determination of the electro-motor force and of the interior resistance of an element of the electric pile; (3) On the relations of heat to the development of flowering plants, especially with regard to the periodic phenomena of vegetation, and on the dynamical influence of solar heat on the evolution of plants; (4) On the mode of reproduction of serpents; (5) On the composition and mutual relations of albuminoid substances; (6) On the coal fields of the basin of Liège. A gold medal of the value of 1000 fr. will be given for the first, fifth, and sixth questions, and of 600 fr. for the second, third, and fourth. The essays must be written in Latin, French, or Flemish. For 1874 the subjects are:—(1) On uric acid and its derivatives, especially in relation to their chemical structure and synthesis; (2) On the polymorphism of the Mucedineæ, their real nature, and the conditions of their development; (3) On the question whether the fungi of fermentation can, under certain circumstances, become changed into the higher fungi, with positive proof of the fact or the contrary.

Harper's Weekly states that Uriah F. Boyden, of Boston, U.S.A., has deposited with the Franklin Institute, of Philadelphia, the sum of one thousand dollars, to be awarded as a premium to any resident of North America who shall determine by experiment whether all rays of light and other physical rays are or are not transmitted with the same velocity. The conditions of the premium limit the applicants to those living north of the southern boundary of Mexico, and including the West India Islands. Applications must be made before the 1st of January, 1873, at which time the judges, appointed by the Franklin Institute, shall examine the memoirs and decide whether any one is entitled to the premium.

WE are desired by Colonel Grant to say that the botanical collection from Tropical Africa, referred to at p. 339, was not made in conjunction with Captain Burton, but during the journey of Captain Speke and himself in 1860-3, from Zanzibar to the great central Lake Region. The results will shortly be published in the Transactions of the Linnean Society; it will be illustrated by 100 (not 600) 4to plates, and the descriptions will be in great part drawn up by Prof. Oliver. We are glad to hear that Mr. W. O. Livingstone, who is accompanying the Livingstone Search Expedition, has considerable botanical knowledge, and is intending to bring home a collection.

IN reference to the hairy tapir of the South American Andes (*Tapirus Roulini*), the acquisition of skeletons of which by the Smithsonian Institution was spoken of in our last number (p. 370), we are informed that a fine series of skins and skeletons of the animal has recently been obtained by Mr. Buckley in Ecuador. Some of these are now in the British Museum; the others have been purchased by Mr. Edwd. Gerrard, jun., of Camden Town. At the last meeting of the Zoological Society a paper was read by Dr. Gray, describing the specimens acquired by the British Museum, and referring them to a new species, *Tapirus leucogenys*. But we are informed that there are no valid grounds for separating them from Roulin's Tapir of the U.S. of Colombia.

WE desire to call attention to the Annual General Meeting of the Iron and Steel Institute, which will be held in Willis's Rooms, King Street, St. James's, London, commencing on Tuesday, March 19, under the presidency of Mr. Henry Bessemer. The programme of proceedings will be found in our advertising columns. It is expected that on Tuesday evening, March 19, a paper, by Mr. I. Lowthian Bell, "On the Conditions which Favour and those which Limit the Economy of Fuel in the

Blast Furnace for Smelting Iron," will be read and discussed at the meeting of the Institute of Civil Engineers, Great George Street, Westminster. The Council have kindly promised to issue invitations to members of the Iron and Steel Institute, to attend on this occasion.

OUR readers will have noticed in our advertising columns the list of subscriptions at present received to the "Priestley Memorial Fund." The object is worthy of the attention of all who are able and disposed to assist in so meritorious an object.

AN important letter, by M. Berthelot, appears in the *Moniteur Scientifique* for February, in which this eminent *savant* insists on the reconciliation of the scientific worlds of France and Germany, pointing out that the united action of France, Germany, and England, in the advancement of civilisation and science, is necessary for the progress of the world.

It is stated that shocks of earthquake were felt at Dresden, Pima, Schandau, Chemnitz, Rodenbach, Weimar, and Rudolstadt, between three and four o'clock on the afternoon of the 6th inst. They continued to recur during an hour, and in some cases several hours.

THE return of Professor C. F. Hartt, of Ithaca, from his late expedition to Brazil, has been already announced in the papers; and we are glad to learn, from *Harper's Weekly*, that he succeeded in making many important discoveries in natural history and the geography of the country, and especially the languages of the native tribes. By his researches in this latter direction he has already become quite an authority, and, we presume, will before long begin to publish his linguistic results. In the course of his expedition Professor Hartt took occasion to examine the great Kjoekkenmoedding, near Santarem, referred to by various travellers, which, however, yielded him only a few fragments of coarse pottery and a few bones. He was very fortunate in the opportunity of excavating the sites of a number of Indian villages on the edge of the bluffs bordering the Amazon and the Tapajos, in the angle made by the two rivers. Here he found an immense quantity of broken pottery, often highly ornamented, idols, stone implements, &c., probably derived from the Tapajos, now extinct as a tribe, or merged into the mixed Indian population of the Amazon. In an ancient burial-place on the Tapajos he dug up a number of burial-pots; none, however, containing complete skeletons. An examination of the mounds of the island of Marajo was to be made by some of his associates who remained behind.

THE Royal Horticultural Society has just issued an exceedingly comprehensive and valuable series of meteorological observations made at their gardens at Chiswick from 1826 to 1864, and analysed by Mr. James Glaisher. The number of tables is nearly sixty, including the mean temperature of every day, and the extremes of mean temperature for every day in each month during the year specified, the excess or deficiency above or below the average of the mean temperature of every day, month, and year; the daily ranges of temperature on every day of the year, and the daily falls of rain in each month. Comparisons are made with the series of observations taken at Greenwich; general conclusions are deduced, and the introductory observations are of value and interest to all meteorologists.

WE understand that the Meteorological Committee have resolved to issue lithographed illustrative charts of the Daily Weather Report, which will be delivered in London, within a reasonable distance from the office of the printer in Lincoln's Inn Fields, between 1 and 2 P.M., or posted in time for the evening mails. Up to the 31st of March these charts will be supplied gratuitously.

AURORA AUSTRALIS

ON Sunday the 4th instant, at 9h. 28m. P.M., my attention was suddenly called to a "fire." Looking in the direction indicated, I saw at S.S.E., about 15° above the horizon, a glare of reddish light. Curious to know whereabouts the supposed fire was, I kept my eyes upon that part of the heavens. Presently, similar patches of light broke out on either side of the first, and in a few seconds I could see, on the assumption made, that there must be several fires blazing away over a wide range, for the sky was here and there lit up with a peculiar dark red light over an extent of at least 70° of the horizon. My attention being now aroused, I had recourse to various conjectures, which were speedily abandoned. The idea of an aurora had occurred almost at the outset; but as I had never, with certainty, seen one in Mauritius, and never heard or read of any having been observed there by others, I felt some reluctance to admit the fact that I was actually witnessing one. My doubts, however, were soon dispelled. I noticed that patches of cloud floating across the illuminated portions of the sky reflected no light, and on one or two occasions, a faint flickering, like lightning, was seen among the upper cirrus clouds. These and other facts, coupled with the knowledge that the magnets had been occasionally disturbed to a considerable extent on Friday and Saturday, and on the morning of Sunday, left no doubt on my mind.

Listening to the house, I immediately mounted a portable inclinometer and declinometer, and took all the measures I could to observe what might take place, dividing my time and attention between the instruments, which I put up in a verandah facing the south, and the aurora right in front of me.

The needle of the inclinometer did not give the slightest indication of a disturbance, but the declinometer magnet was affected to the extent at times of 9'.

It was 9h. 48m., or 20m. after I saw the luminosity supposed to have been caused by a fire, that I began to observe the aurora systematically, and I append a copy of the notes which I took from that time up to the 20m. A.M.

What struck me particularly was the apparent quietness of the whole scene. Unlike the "merry dancers," which I have often seen and admired in Scotland, rapidly changing shape and colour, and rushing in variegated columns and bands in different directions with great velocity, thereby conveying an impression of energy and violence, the display of Sunday night was calm and serene, giving one an idea of peace and repose. Except shortly after I first saw the phenomenon, I could not make out any motion of the arches, segments, or luminous bands. They appeared and disappeared without change of locality, the intensity of the light increasing or decreasing without any flickering. I could see no shooting, darting, or rushing of the bands or beams. Each made its appearance and disappearance simultaneously along its whole length, as if the action was vertical.

The spectacle presented by the beams from 11 P.M. to 11.20 P.M. was at once grand and lovely beyond description. Almost from the extreme left to the extreme right, and from as low down as I could see up to a meridional altitude of about 72°, the sky was furrowed with alternate white and dark bands, all of which, so far as I could judge, were parallel to each other and to the magnetic meridian. They were generally at unequal intervals, sometimes crowded together, and sometimes considerably apart; but in this respect I could only judge of those near the meridian. At times they presented the appearance of graceful folds and convolutions, but the action seems to have been performed so gently and imperceptibly as to convey no idea of motion. They presented the same colour during the whole time, namely, a steel grey to a silver white.

The arches and segments were of a blood, cherry, or Indian red, and every now and then, when the intensity of the light increased, the stars twinkled like gems seen through a delicate pink curtain or veil placed before them. Occasionally one could fancy that he was looking at the Southern Cross through very transparent glass or crystal of an exquisite ruby tint into an inner chamber lit up with light of a similar colour.

The light was never very strong. I saw no part of the landscape lighted up by reflection. It is to be borne in mind, however, that I was occupied with the instruments, and that much may have escaped my attention.

During some parts of the night black clouds passed over the field of view, and I believe, although I could not see them, except on one or two occasions, that they were light cirrus and

cirro-stratus clouds in the upper regions, as had been the case throughout the day.

The wind was light from E. by S. throughout, and the barometer was 100 inch below the mean for the season.

After 1 A.M. the aurora speedily died away. At 3 A.M. I could see nothing; but looking out at 4.30 A.M. I saw a red glow in the southward, which at first I took for aurora, but which turned out to be cirrus clouds lit up in the early dawn.

Throughout Monday the magnets were quiet. A great many cirri appeared, which, in the evening, assumed at eastward and westward a dark red colour, very much resembling that of the aurora.

The Magnetic Observatory, which had barely commenced operations, may be said to have been inaugurated on Sunday night, and it is possible that its future records will show, amongst other things, that aurora is not so frequent in Mauritius as is supposed, although such a display as that which has just occurred I may not be seen for many years to come. In the end of August and beginning of September, 1859, aurora was observed over a considerable portion of both hemispheres, and on one night during that period I saw a reddish glow in our southern sky, which may have been the Aurora Australis. Probably the present display has been seen over a great part of the globe. Has any unusual solar activity been observed? On Friday a chain of spots stretched over nearly the whole of the sun's disc, and a large group occupied another part of it. On Monday the chain had disappeared. Any one who may have made observations in the colony or at sea on Sunday night would oblige me by sending them to the Observatory. It would be interesting to know the height of the aurora.

Aurora Australis seen at Mauritius on the 4th to 5th February, 1872.

9.48 P.M.—An irregular convex arch of dark red light extending over about 60° of the horizon, and having its vertex in the line of the magnetic meridian. Brightest below the Southern Cross.

9.58 P.M.—An arch of a dark red colour having a cord of about 70°. Vertex in or near the magnetic meridian. Patches of black cloud passing over the coloured segment from N. E. by S., but they reflect no light.

10.1 P.M.—The segment is of a more intense dark red colour. Its eastern limit is about 3° east of the Cross, and its brightest portion from 1° to 2° above the Cross. It is broken off towards the west, and extends in that direction to about only S. by W.

10.4 P.M.—No segment now seen, but patches of Indian or cherry red on either side of the magnetic meridian at a distance of 30° to 40° from it.

10.8 P.M.—The whole has almost disappeared.

10.19 P.M.—An intense blood-red patch at S.S.E. having its centre 2° to 3° below the Cross. The stars shining through it with subdued light.

10.20 P.M.—The red light all gone, but a broad conical space of an ash-grey colour, with a slight green tinge, low down on the horizon, and apparently bisected by the magnetic meridian. Resembling early dawn.

10.22 P.M.—A dimly defined arch of a smoky red colour extends from about E.S.E. to S.W. by W. The height of its vertex is about 40° above the horizon.

10.24 P.M.—All gone.

10.25 to 10.30 P.M.—Appearing and disappearing. Some faint streaks of whitish light seen low down.

10.34 P.M.—Six bands of faint whitish light near horizon at S. by E.

10.37 P.M.—A bright meteor of first magnitude travelled slowly from a Centauri towards N. by E. It had a train of light and left sparks behind it. Colour white with a yellow tinge. The auroral bands brighter and higher.

11 P.M.—Sixteen luminous bands of a steel grey to a silver white colour, extending from as low down as I can see to within 20° of the zenith. The extremity of one of them is close to Canopus. Light of the Great Magellan cloud enfeebled. No apparent convergence of the beams; they seem to be quite parallel.

11.6 P.M.—The parallel bands are still seen. They cover the greater part of the hemisphere, extending (at the meridian) to about 72° above the horizon. On their eastern and western extremes there are patches of blood-red light, but none in the intermediate space. Some of the bands appear to be folded in a direction from west to east.

11.7 P.M.—Dying away.

11.15 P.M.—A deep red glow from E. to W. by S. along the horizon. Fourteen parallel bands of a silvery colour, with dark bands between them. They lie south and north, occupying nearly the whole southern hemisphere as far as the eye can reach, and are flanked at east and west by patches of blood and cherry red.

11.24 P.M.—The bands have disappeared. There is a deep red glare at E.S.E. and a lighter one at W.S.W.

11.28 P.M.—A few faint bands on either side of Canopus. A red light on their western, but none on their eastern side.

11.31 P.M.—A dark red glow at W.S.W., about 12° above the horizon.

11.33 P.M.—Clouds gathering in the lower regions of the atmosphere.

11.37 P.M.—Two parallel faint beams of whitish light 2° to 3° east of Canopus. A faint red glow at W.S.W., about 10° above the horizon.

11.42 P.M.—Two broad bands of faint whitish light to westward and three to eastward of Canopus. A patch of red light still at W.S.W. near horizon.

11.46 P.M.—Clouds gone. Aurora gone.

11.49 P.M.—A faint red glow at W.S.W. about 10° above the horizon, and a band of faint greyish light about 2° west of Canopus.

11.51 P.M.—The glow at W.S.W. is brighter and higher.

11.58 P.M.—Much fainter.

0.34 A.M.—A segment of dark red light from S.E. by S. to W.S.W., and rising at its middle to about 45° above the horizon.

1.20 A.M.—A bright red glow from S.E. to S.W. Intensest below the Centaur. Soon died away. J. MELDRUM

Royal Alfred Observatory, Mauritius, February 6

GEOLOGY

Supposed Legs of Trilobites*

MR. HENRY WOODWARD, of the British Museum, in a reply to the paper by the writer in vol. i, p. 320, of the present series of this Journal, supports the view that the supposed legs are real legs. He says that the remark that the calcified arches were plainly a calcified portion of the membrane or skin of the under surface is "an error, arising from the supposition that the matrix represented a part of the organism." But Prof. Verrill, Mr. Smith, and myself, are confident that there is on the specimen an impression of the skin of the under surface, and that this surface extended and connected with the arches, so that all belonged distinctly together.

Moreover the arches are exceedingly slender, far too much so for the free legs of so large an animal; the diameter of the joints is hardly more than a sixteenth of an inch outside measure; and hence there is no room inside for the required muscles. In fact, legs with such proportions do not belong to the class of Crustaceans. Moreover the shell (if it is the shell of a leg instead of a calcified arch) is relatively thick, and this makes the matter worse.

We still hold that the regular spacing of these arches along the under surface renders it very improbable that they were legs. Had they been closely crowded together, this argument would be of less weight; but while so very slender, they are a fourth of an inch apart. Mr. Woodward's comparison between the usual form of the arches in a *Macrouran* and that in the trilobite does not appear to us to prove anything. We therefore still believe that the specimen does not give us any knowledge of the actual legs of the trilobite. Mr. Woodward's paper is contained in vol. vii., No. 7, of the *Geological Magazine*.

PHYSIOLOGY

Blood Crystals

AN interesting volume has just been published by M. W. Preyer on Blood Crystals. The literature of this subject, which dates no farther back than 1840, is already extensive, no less than 143 authors being quoted in the "Bibliography," some of whom, as Böttcher, Hoppe-Seyler, Kühne, Lehmann, Rollett, Valentin, and M. Preyer himself, have written many separate

essays on points bearing more or less directly upon the crystallisation of the blood. Though blood crystals were first observed by Hünefeld, the merit of discovering them is due to Reichert, who first recognised their nature. The fact of the crystallisation of a complex organic substance like blood was first received with some amount of incredulity, but the corroborative testimony of many microscopists soon cleared away all doubt, and a variety of methods were suggested by which the crystals could be obtained. The best plan for obtaining them is thus given by M. Preyer. The blood is received into a cup, allowed to coagulate, and placed in a cool room for twenty-four hours. The serum is then poured off, and a gentle current of cold distilled water passed over the finely divided clot placed upon a filter until the filtrate gives scarcely any precipitate with bichloride of mercury. A current of warm water (30°—40° Cent.) is now poured on the clot, and the filtrate received in a large cylinder standing in ice. Of this a small quantity is taken, and alcohol added drop by drop till a precipitate falls from which an estimate may be made of the quantity required to be added to the whole *without* producing a precipitate. The mixture, still placed in ice, after the lapse of a few hours, furnishes a rich crop of crystals. The forms of the crystals, obtained from the blood of different animals do not vary to any great extent, and are all reducible to the rhombic and hexagonal systems. The vast majority are rhombic prisms, more or less resembling that of man. The squirrel, however, with several of the *Kodentia*, as the mouse and rat, and the hamster, are hexagonal. The hemoglobin of several corpuscles is required to form a single crystal. All blood crystals are double refracting. The animals whose blood has been hitherto examined and found to crystallise, are—man, monkey, bat, hedgehog, mole, cat, lion, puma, fox, dog, guinea pig, squirrel, mouse, rat, rabbit, hamster, marmot, ox, sheep, horse, pig, owl, raven, crow, ruck, sparrow, pigeon, goose, lizard, tortoise, serpent, frog, dooble, carp, barbel, bream, rudd, perch, herring, flounder, pike, garpike, earthworm, and nephelis. The spectrum of blood-colouring matter when oxidised with its two absorption striae between D and E of Fraunhofer's lines or in the yellow part of the ordinary spectrum, and the single band of deoxidised hemoglobin, are now well known. M. Preyer states he has not been able to obtain a spectrum from a single blood corpuscle, but that the characteristic bands are visible where certainly only a very few are present. The specific gravity of dry hemoglobin he gives at about 1.3—1.4. The solubility of the crystals obtained from different animals varies considerably. Those of the guinea-pig and squirrel dissolving in water with great difficulty. Hemoglobin is insoluble in absolute alcohol, ether, and the volatile and fixed oils, in benzole, turpentine, chloroform, and bichloride of carbon. It is easily soluble in alkalies, acids rapidly decompose it. He calculates out for it the fearful formula of $C_{600}H_{960}N_{124}Fe, S_8O_{179}$, as agreeing very accurately with the percentage results of its analysis. Its equivalent is 4444.4. Many pages of M. Preyer's work are occupied with an account of the action of various reagents upon it. The plates contain the forms of the principal crystals, and thirty-two spectra lithographed in colours. He describes five crystallisable products of the decomposition of hemoglobin, namely, hemin, hematosin, hematoidin, hematochlorin, and hematoalbumin, and several uncrystallisable, such as methemoglobin, hematin, and hemathion.

H. P.

SCIENTIFIC SERIALS

Annalen der Chemie und Pharmacie, September 1871.—Kochlin has continued his researches on "compounds of the camphor group." By the action of nitric acid on camphor the author has obtained a new body, $C_{27}H_{44}O_5$, which he calls camphoronic acid, and which has the property of forming salts in which H_2 and H_3 are replaced by metals. By distillation with potassic hydrate, butyric acid is produced; with bromine in presence of water camphoronic acid is oxidised, yielding oxy-camphoronic acid; this acid forms salts, in which H_1 , H_2 , and H_3 are replaced by metals.—An important physiologico-chemical paper follows by Hlasiwetz and Habermann on "Proteids," and a paper by Naumann on the length of time for the evaporation and condensation of solid bodies," which, however, do not possess much general interest.—Bender contributes a paper on the "hydrate of magnesian oxychloride." This substance, however, does not appear to be very stable, or to have very marked properties.—Mulder has experimented on allantoin and bodies

* From the *American Journal of Science and Arts* for March 1872.

derived therefrom; by the action of nitric acid two substances are obtained, allanic and allanturic acid.—An interesting paper on a new series of aromatic hydrocarbons, by Zincke, follows; by heating together benzol, benzyl-chloride and zinc powder, or finely divided copper, a reaction sets in with the evolution of hydrochloric acid gas, and the partial formation of a metallic chloride; the principal reaction seems to be, however, $C_7H_5Cl + C_7H_6 = C_{13}H_{12} + HCl$. Benzyl-benzol is a solid crystalline body, melting at $26^\circ-27^\circ$, and boiling at $261^\circ-262^\circ$; by oxidation it is transformed into $C_{13}H_{10}O$, a crystalline body belonging to the monoclinic system, which fuses at $25^\circ-26^\circ$. Benzophenone, however, has the same composition, but crystallises in the rhombic system, and fuses at $48^\circ-49^\circ$; the body obtained above is therefore an isomeric benzophenone, it, however, easily passes into the modification fusing at $48^\circ-49^\circ$. The composition of benzyl-benzol will there be probably be $C_6H_5-CH_2-C_6H_5$.—This number concludes with the translations of two papers by Messrs. Friswell and Armstrong respectively, which have already appeared in the English journals.

THE *Geological Magazine* for January (No. 91) opens with a paper on a subject connected with an important branch of geology which is too much neglected in this country, and, indeed, has but few cultivators anywhere, namely, the microscopic structure of the so-called igneous rocks. This is Mr. S. Allport's notice of the microscopic structure of the pitchstones of Arran, the appearance of the sections of which under the microscope is, as described by Mr. Allport, exceedingly beautiful; and it is to be hoped that this paper and the illustrations accompanying it may induce others to enter upon this most interesting and important line of research.—The Rev. O. Fisher contributes a note on "Cirques and Taluses," with reference to Mr. Bonney's paper in the December number of the magazine. Mr. Fisher ascribes an essential part in the excavation of cirques to glacial action.—Mr. D. Forbes communicates a severe criticism of some remarks made by Mr. A. H. Green in his account of the geology of part of the county of Donegal.—"The Age of Floating Ice in North Wales" is the subject of a paper by Mr. D. Mackintosh; and Mr. James Geikie publishes the second part of his "Memoir on Changes of Climate during the Glacial Epoch."—The number includes the usual notices and reviews.

Mémoires de la Société des Sciences Naturelles de Cherbourg. Tome xv. (Deuxième Série, Tome v.) 1870. "On the Swell and Roll of the Sea," by W. Bertin.—"Notes on the Comora and Seychelles Archipelagos," by M. Jouan. These islands were visited in 1850; a very brief list of the flora and fauna is appended. The list of birds has been apparently overlooked in the Zoological Record for January 1870.—"Notes on the Tubercles met with in *Callitriche autumnalis*," by MM. Karslschikoff and Rosanoff, with a plate.—"On the *Lophobranchs*," by M. Dameril.—"Notes of a Visit to Aden, Point de Galle, Singapore, and Tché-fou," by M. Jouan.—"On the Influence of Climate on the Growth of some Resinous Trees," by M. Békétoff.—"Geological Essay on the Department of La Manche," by M. Bonissent. "Supplementary notes to a paper on the Swell and Roll of the Sea," by M. Bertin.—Works received by the Society from July 1869 to August 1870.

Proceedings of the Natural History Society of Dublin, for the Session 1869-70, 1870-71, vol. vi., part i. (Dublin 1871) contains the following papers by Dr. A. W. Fox:—1, Notes on Irish Lepidoptera; 2, On Goitre in Animals; 3, On the Breeding of some Birds from the Southern Hemisphere in the Dublin Zoological Gardens; 4, Notes on Animal Luminosity; 5, Notes on Entomology; 6, Notes on Irish Diptera; 7, On some Irish Hymenoptera; and the following by Mr. William Andrews:—1, On the Inhabitants of the Rock-pools and caves of Dingle Bay, records, as new to the fauna of Ireland, *Altipia couchii*, *Stomphix churchii*, *Balanophyllia regia*, *Caprea sanguinea*, and "a deep-water species of stony coral, formed by hydroid animals, and related to the Tabulate Madreporæ, which is nearly allied to, and indeed considered identical with, *Millepora alcinoris* of Linneus;" 2, Ichthyological Notes; 3, On *Orthogoriscus oblongus*, with two plates; 4, On some rare Crustacea from the south-west of Ireland; 5, On the Ichthyology of the south-west of Ireland; 6, Notes on Hymenophylla, especially with reference to New Zealand species; 7, On some Irish Saxifragæ; also papers by Prof. Macalister, on the mode of growth of Discoid and Turbinate shells; by G. H. Kinahan, on the Ferns of West Connaught and the south-west of Mayo.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 7.—"On the organisation of the Fossil Plants of the Coal-measures.—Part III. *Lycopodiaceæ*." By Prof. W. C. Williamson, F.R.S. An outline of the subject of this memoir has already been published in the Proceedings in a letter to Dr. Sharpey. In a former memoir the author described the structure of a series of Lepidodendroid stems, apparently belonging to different genera and species. He now describes a very similar series, but all of which, there is strong reason for believing, belong to the same plant, of which the structure has varied at different stages of its growth. The specimens were obtained from some thin fossiliferous deposits discovered by Mr. G. Grieve, of Burntisland, in Fifeshire, where they occur imbedded in igneous rocks. The examples vary from the very youngest half-developed twigs, not more than $\frac{1}{16}$ th of an inch in diameter, to arborescent stems having a circumference of from two to three feet. The youngest twigs are composed of ordinary parenchyma, and the imperfectly developed leaves which clothe them externally have the same structure. In the interior of the twig there is a single bundle, consisting of a limited number of barrel vessels." In the centre of the bundle there can always be detected a small amount of primitive cellular tissue, which is a rudimentary pith. As the twig expanded into a branch, this central pith enlarged by multiplication of its cells, and the vascular bundle in like manner increased in size through a corresponding increase in the number of its vessels. The latter structure thus became converted into the vascular cylinder so common amongst Lepidodendroid plants, in transverse sections of which the vessels do not appear arranged in radiating series. Simultaneously with these changes the thick parenchymatous outer layer becomes differentiated. At first but two layers can be distinguished—a thin inner one, in which the cells have square ends, and are disposed in irregular vertical columns, and a thick outer one consisting of parenchyma, the same as the epidermal layer of the author's preceding memoir. In a short time a third layer was developed between these two.

When the vascular cylinder had undergone a considerable increase in its size and in the number of its vessels, a new element made its appearance. An exogenous growth of vessels took place in a cambium layer, which invested the pre-existing vascular cylinder. The author distinguishes the latter as the vascular medullary cylinder, and the former as the ligneous zone. The newly-added vessels were arranged in radiating laminae, separated from each other by small but very distinct medullary rays. At an earlier stage of growth traces of vascular bundles proceeding from the central cylinder to the leaves had been detected. These are now very clearly seen to leave the surface of the medullary vascular cylinder where it and the ligneous zone are in mutual contact; hence tangential sections of the former exhibit no traces of these bundles, but similar sections of the ligneous zone present them at regular intervals and in quincuncial order. Each bundle passes outwards through the ligneous zone, imbedded in a cellular mass, which corresponds, alike in its origin and in its direction, with the ordinary medullary rays, differing from them only in its larger dimensions. At this stage of growth the plant is obviously identical with the *Diploxylon* of Corda, with the *Anabathra* of Witham, and so far as this internal axis is concerned, with the *Sigillaria elegans* of Brongniart. The peculiar medullary vascular cylinder existing in all these plants is now shown to be merely the developed vascular bundle of ordinary Lycopods, whilst the exogenous radiating ligneous zone enclosing that cylinder is an additional element which has no counterpart amongst the living forms of this group.

Though the central compound cellulose-vascular axis continued to increase in size with the general growth of the plant, it was always small in proportion to the size of the stem. The chief enlargement of the latter was due to the growth of the bark, which exhibited three very distinct layers,—an inner one of cells with square ends, and slightly elongated vertically and arranged in irregular vertical rows, an intermediate one of prosenchyma, and an outer one of parenchyma. These conditions became yet further modified in old stems. The exogenous ligneous zone became very thick in proportion to the medullary vascular cylinder, and the differences between the layers of the bark became yet more distinct. These differences became the most marked in the prosenchymatous layer; at its inner surface the cells are prosenchymatous, but towards its exterior they become yet more elongated vertically, their ends being almost square,

whilst numbers of them of exactly equal length are arranged in lines radiating from within outwards. These oblong cells often pass into a yet more elongated series with somewhat thickened walls, which become almost vascular, constituting a series of bast-fibres. In the transverse sections these prosenchymatous cells are always arranged, like the vessels of the ligneous zone, in radiating lines. Yet more external is the sub-epidermal parenchyma passing into leaves composed of the same kind of tissue. The petioles of the leaves have been long, if not permanently, retained in connection with the stem, a character of Corda's genus *Lomatophloios*.

Where young twigs branch, the vascular medullary cylinder divides longitudinally into two parts; the transverse section of this cylinder now resembles two horse-shoes pointing in opposite directions. The break in the continuity of each half of the cylinder occasioned by the division is never closed by new vessels belonging to the cylinder; but when the stem develops exogenously, the cambium-layer, from which the new growths originated, has endeavoured to surround these openings in the cylinder, and, by closing them, once more to separate the medullary from the cortical tissues. Some beautiful specimens have been obtained, which exhibit these new exogenous layers in process of formation. The vessels of the young layers are not half developed. At first they meander vertically through masses of delicate cellular tissue; but they soon arrange themselves in regular radiating vessels and cells, becoming more outward prolongations of the woody wedges and medullary rays of the older part of the stem. At this stage of their growth, the walls of the vessels are deeply indented by the contiguous cells, as if the plastic issues of the former had been moulded upon the latter structures. As the new vessels enlarge, the superfluous intervening cells disappear, until each medullary ray finally consists of a single vertical pile of from one to a small number of cells, arranged in as many Conifera. The exceptional cases are those where vascular bundles pass outwards to the leaves; these bundles have protected the contiguous cells above and below them from the pressure of the enlarging ligneous vessels and limited their absorption. Both these and the smaller ordinary rays pass outwards in horizontal and parallel lines. The evidences of an exogenous mode of growth afforded by these young, half-developed layers of wood is clear and decisive.

The Burntisland deposits are full of fragments of strobili, especially of tor sporangia and of macrospores. Several fine *Lepidostrobus* have been obtained, like those to which the fragments have belonged, and which the author believes to have been the fruits of the stems described. The structure of these strobili is very clear and of interest; the primary branches from the central axis subdivide, so that each sporangium rests upon a separate bract, from the upper surface of which a vertical lamina arises, and, extending the entire length of the sporangium, ascends far into its interior, where it bifurcates. The cellular walls of the sporangium blend with the bract along each side of this sporangio-phore. The microspores occupy the upper part of the *Lepidostrobus*, and are usually triplospores, sometimes tetraspores. The macrospores occupy the lowermost sporangia, are of large size, and are very remarkable from having their external surfaces clothed with numerous projecting caudate appendages, each one of which is slightly capitate at its extremity. So far as the author is aware, this is an undescribed form of macrospore.

Two new forms of *Lepidodendron* are described from the Oldham beds, in one of which the medullary axis attains to an unusually large size, even in the young shoots; whilst the other is remarkable for the magnitude of its leaves. It is obvious that the plant which is the chief subject of the memoir is a true example of Corda's genus *Diploxylon*, so far as its woody axis is concerned; whilst its bark and leaves are those of a *Lomatophloios*, and its slender twigs are *Lepidodendron*. The author also points out the probability that the plant had a true Stigmarian root.

The structure of these fossil types is compared with that of recent *Lycopodiaceae*. The vascular medullary cylinder is shown to be an aggregation of the foliar vascular bundles, so that the vascular connection between the leaves and the stem is maintained exclusively by means of these vessels, which thus correspond most closely with the central vascular axes of living Lycopods. On the other hand, the exogenous layers do not communicate directly with the leaves in any way; but, on the other hand, they are homologous with the corresponding layers in the Stigmarian root, in which latter they receive the vascular bundles from the rootlets. The medullary cylinder does not enter the

roots, but appears to terminate at the base of the stem, though the pith is prolonged through them. Hence it seems probable that the nutritive matters were taken up from the soil by the Stigmarian rootlets, that it ascended into the *Diploxylon* stem through the exogenous layer, but that, in order to reach the leaves, if conveyed by the vessels, and not by the cellular tissues, it had to be transferred by endosmosis to those of the medullary cylinder. The bark of the fossil plants is compared with those of *Lycopodium chamecyparissus*, and *Selaginella Martensii*, which two combined represent the former.

These discoveries necessitate some changes in generic nomenclature, since the several parts of the plant not only represent the three genera above mentioned, but also several others. Meanwhile some other errors require correction. Corda erroneously defined his genus *Diploxylon* as having no medullary rays, and Brongniart relied upon this distinction in separating *Diploxylon* from *Sigillaria*; but no difference exists between the ligneous structures of the two genera, so far as *Sigillaria* is illustrated by Brongniart's *S. elegans*. Corda, Brongniart, and King all agree in regarding *Diploxylon* (which is identical with Witham's *Anabathra*) as a Gymnospermous Exogen. The necessity for abandoning this separation of the plants in question from the *Lycopodiaceae*, urged in the author's previous memoir, is now made more obvious than before, the distinctions upon which the great French botanist relied in his classification being now shown to be such as mere differences of age can produce. The author concludes from his own observations that the genera *Diploxylon*, *Anabathra*, *Lomatophloios*, and *Leptoxylon* must be united. Brongniart had already brought into one generic group Corda's genera *Lomatophloios*, *Leptoxylon*, and *Calamoxylon*, Göppert's genus *Pachyphylum*, and Sternberg's genus *Lepidophloios*, giving the latter name to the whole. Hence no less than six obsolete generic names are disposed of. The author finally follows Brongniart in adopting the term *Lepidophloios*, and temporarily assigns to the plant described the trivial name of *L. brevifolium*. The further relations of this genus to more ordinary forms of *Lepidodendron* require further investigation.

Linnean Society, March 7.—Mr. G. Bentham, president, in the chair. "Revision of the genera and species of *Scilla*," by J. G. Baker. This paper contained technical details of the new groups and genera proposed of this difficult tribe of Liliaceae in continuation of papers already presented to the society.—"On the *Androcium* in *Cochlostoma*," by Dr. M. T. Masters. In this singular genus of Comelyaceae, from the Amazon region, the staminal arrangement is different to anything else observed in the vegetable kingdom. There are three petaloid stamens, all arranged on the posterior side of the pistil, within which are three spiral bodies constituting the anthers. Within these are three staminodes, one of which is not developed till a considerably later stage than the other two; they do not appear to have any physiological value. The mode of fertilisation is obscure; the stamens and styles are both so completely obscured that self-fertilisation seems impossible.—"On a supposed hybrid between *Vaccinium Myrtillus* and *V. Vitis-Idea*," by Mr. Gardner. In the discussion which followed, the prevalent opinion was that the plant was but a variety of *V. Vitis-Idea*.—"A list of the Marine Algae of St. Helena," by Dr. Dickie. These are twenty-one in number, all dwarf, and notwithstanding the remarkable peculiarity of the terrestrial vegetation, only one species is peculiar to the island.—"Catalogue of new *Leguminosae* from Western India," by N. A. Dalzell.

Chemical Society, March 7.—Prof. Williamson, F.R.S., vice-president, in the chair.—In the course of the ordinary business of the society, the proposed changes in the officers and council of the society for the ensuing year were announced.—Dr. Debus, F.R.S., then read a paper "On the reduction of ethylic oxalate by sodium amalgam." In 1864 Dr. Friedlander described, as the result of this reaction, the production of the sodium salt of a new acid, which he named glycolinic acid. Although the author has carefully repeated Dr. Friedlander's experiments, and varied the details of the process in different ways, he has been unable to obtain glycolinic acid, the only acids formed being glycollic and tartaric. A comparison of the crystalline form of a specimen of sodium glycolinate, prepared by Friedlander, with that of sodium glycolate, would seem to indicate that it is identical with the latter.—Two other papers were read, one "On metastannic acid, and the detection and estimation of tin," by A. H. Allen; and the other, "Note on the quantity of cesium contained in the water of the

hot springs found in Wheal Clifford," by Colonel Philip Yorke, F.R.S., from which it appears that a gallon of this water contains 26 grs. of lithium chloride and one million parts 1·7 of caesium chloride, or more than ten times as much of the latter as the Dürkheim water, in which, it will be remembered, that element was first detected by Kirchhoff and Bunsen in 1860.

Zoological Society, March 5.—Mr. John Gould, F.R.S., vice-president, in the chair. Mr. Howard Saunders exhibited and made remarks on specimens of *Falco barbarus* and *Cypselus pallidus*, obtained in Southern Spain, being the first recorded occurrences of these species on the continent of Europe.—A letter was read from Mr. Walter J. Scott, of Queensland, giving some further information respecting the supposed existence of an undescribed large carnivorous animal in that colony. This letter was accompanied by drawings of the impression of the foot of the animal.—Mr. A. H. Garrod read some notes taken on the dissection of an ostrich, recently living in the Society's menagerie. The examination of this bird proved that its death was due to copper poisoning, a number of copper coins and pieces of coin in a much worn state having been found in its stomach.—Mr. E. W. H. Holdsworth read a paper containing a catalogue of the birds found in Ceylon, with remarks on their localities and geographical distribution; and gave a description of two new species, which were proposed to be called *Zosterops ceylonensis* and *Arremona blighi*. The total number of Ceylonese birds included in Mr. Holdsworth's list was 323, of which 36 were stated to be peculiar to the island.—A communication was read from Dr. Hermann Burmeister, containing a list of the species of the Lamelli-rostral birds of the Argentine Republic, with remarks on their habits and times of occurrence.—A communication was read from Dr. W. Peters, containing a list of a collection of small mammalia recently made by Mr. J. J. Monteiro in Angola.—Dr. J. E. Gray communicated some notes on a new species of tapir (*Tapirus leucogaster*) from the snowy regions of the Cordilleras of Ecuador, recently obtained by Mr. Buckley; to which were added some observations on the young spotted tapirs of Tropical America.

Society of Biblical Archæology, March 5.—Dr. Birch, president, in the chair.—Mr. J. W. Bosanquet read a paper "Concerning Cyrus, son of Cambyse, grandson of Astyages, who took Babylon; as distinguished from Cyrus, father of Cambyse, who conquered Astyages." In this paper, the learned chronologist endeavoured to show that, contrary to the received opinion of historians, Cyrus, son of Cambyse, though leader of the Medes as early as the year B.C. 535, was contemporary with the early part of the reign of Darius Hystaspes; having taken the throne of the Persian Empire after the death of his father. This view he believed to be consonant with the results of recent discoveries, and afforded a satisfactory explanation of the confessedly difficult chronology of Ezra and the Chaldee writers. Mr. Bosanquet summed up his argument as having proved:—(1) that Cyrus, father of Cambyse, who conquered Astyages, neither conquered Babylon nor reigned in Babylon, as Ptolemy assumes in his Babylonian Canon; (2) that Cyrus, son of Cambyse, King of Persia, grandson of Astyages, twice conquered Babylon; but did not reign over Babylon till after his father's death in B.C. 518; (3) that Ptolemy's Canon rests upon no sound authority, either historical or astronomical, as regards placing the reign of Cyrus at Babylon before the reign of Cambyse; (4) that the alternative reckoning deduced from Demetrius is to be preferred to that of Ptolemy, as resting upon the dates of three solar eclipses.

Anthropological Institute, March 4.—Mr. G. Harris, vice-president, in the chair.—Mr. Charles F. Tyrwhitt Drake was elected a member.—Captain Richard F. Burton read his third paper "On Anthropological Collections from the Holy Land." It contained accounts of the Hamath Inscriptions, facsimiles of which were exhibited, and of skulls from Siloam. An interesting discussion was raised on the high antiquity of the Hamath Inscriptions. Dr. Carter Blake described the human remains brought by Captain Burton from Siloam, and by M. Ganneau from the "Tomb of Jesus," near that place; the former were stated to be undoubtedly Jewish, and the latter of modern Turkish origin. Mr. J. Gould Avery read a paper "On Race-characteristics as related to Civilisation."

THE HISTORY OF THE ROYAL
INSTITUTION*

NO other Institution has been so closely associated with the greatest discoveries of Chemical and Physical Science during the present century as that which has its abode in the well-known building in Albemarle Street. The names of Rumford, Banks, Young, Davy, Faraday, Tyndall, will always add lustre to its annals; nor will it be forgotten that in its laboratory were made the most famous discoveries of Davy and Faraday. Dr. Bence Jones gives us in this very interesting volume a sketch of the history of the Institution, derived from its own record of proceedings, interspersed with biographical notices of its founder, Count Rumford, and its most eminent professors, Garnett, Young, and Davy. Of Faraday we hear comparatively little, Dr. Bence Jones having sketched his life in a separate biography; and with regard to the eminent men whose present connection with the Institution is adding fresh popularity to its courses of lectures, he is altogether silent.

Probably few of the visitors who now attend the lectures at the Royal Institution, or who crowd to its fashionable Friday evening *réunions*, are aware of the object with which it was originally founded, as shown in the prospectus drawn up by Count Rumford in 1799, from which the following are extracts:—

"Proposals for forming by subscription, in the metropolis of the British Empire, a public Institution for diffusing the knowledge and facilitating the general introduction of useful mechanical inventions and improvements, and for teaching by courses of philosophical lectures and experiments the application of science to the common purposes of life:—

"The two great objects of the Institution being the speedy and general diffusion of the knowledge of all new and useful improvements, in whatever quarter of the world they may originate, and teaching the application of scientific discoveries to the improvement of arts and manufactures in this country, and to the increase of domestic comfort and convenience, these objects will be constantly had in view, not only in the arrangement and execution of the plan, but also in the future management of the Institution.

"As much care will be taken to confine the establishment within its proper limits as to place it on a solid foundation, and to render it an ornament to the capital and an honour to the British nation.

"In order to carry into effect the second object of the Institution, namely, 'Teaching the application of science to the useful purposes of life,' a lecture-room will be fitted up for philosophical lectures and experiments, and a complete laboratory and philosophical apparatus, with the necessary instruments, will be provided for making chemical and other philosophical experiments."

This basis was adhered to, and these eminently practical objects were steadily kept in view, as long as the management remained with the original founders of the Institution; but it soon passed into the second stage of its existence. Count Rumford had fixed his residence abroad

during the latter years of his life, the eminent men whom he had collected around him, headed by his intimate friend and ally, Sir Joseph Banks, withdrew from its active management, and its control passed into the hands of others, whose chief aim was to recruit its exhausted funds by making the Royal Institution one of the most fashionable places of resort in London. In this they succeeded; but their success was mainly due to the extraordinary interest which centred round the remarkable discoveries of young Davy which signalled the early years of the century. When we read the history of these discoveries, following one another in quick succession—the determination of the true constitution of the alkalis and alkaline earths, potassa, soda, lime, magnesia, the decomposition of ammonia—each a link in the chain of investigation which produced a complete revolution in chemical philosophy, we are disposed to query whether future diligent workers in the fields of science will ever again be rewarded by discoveries of similar gigantic importance.

The sketch of the life of Sir Benjamin Thompson, Count Rumford of the Holy Roman Empire, as presented by Dr. Bence Jones, shows a character full of strange contradictions. A native of North America, during the War of Independence an ardent Royalist, and throughout his life imbued with aristocratic principles of the strongest tinge, he yet spent all his energies in physical discoveries and mechanical inventions calculated to ameliorate the condition of the masses, and to promote the health and comfort of their lives. It was indeed for the purpose of forwarding this object mainly, as we have seen, that he projected the establishment of the Royal Institution. A man of the warmest affections, he yet compelled his second wife (Lavoisier's widow), to seek relief from domestic unhappiness in a judicial separation. With a remarkable power of attracting around him, and moulding to his views, the most eminent men in various branches of science, there were yet few whom he did not estrange from him by his morbid jealousy, and by the eccentricity of his conduct. The littleness of his character will, however, be forgotten in the noble aims and great results of his life.

We are glad to have recalled to us in this volume the career of so disinterested a student of Science as Dr. Thomas Young, and to find a full recognition of his eminent position as the *avant-courier* of Davy and Faraday. Born in Somersetshire in 1773, he showed in his school-boy days that precocity of intellect and power of acquiring knowledge in almost any subject presented to him, which does not always mark the future genius. After spending the years from fourteen to nineteen as a private tutor, he became in 1793 a student at St. Bartholomew's Hospital, presented during the same year a paper to the Royal Society on the "Structure of the Crystalline Lens," and in 1794, at the age of twenty-one, was elected a Fellow of that body. From 1799 to 1801 Dr. Young was carrying on his remarkable series of experiments on Sound and Light, and in the latter year was appointed Professor of Natural Philosophy to the Royal Institution. His lectures however were not considered sufficiently popular for the audiences that then frequented it, and his connection with it terminated in 1803. During the next twenty years of his life he practised as a physician in London, being connected with St. George's Hospital. In 1818 he was appointed

* "The Royal Institution: Its Founders and its First Professors." By Dr. Bence Jones, Honorary Secretary. (London: Longmans and Co. 1871.)

superintendent of the "Nautical Almanack" and secretary of the Board of Longitude, and in 1827, on the resignation of Sir Humphry Davy, was spoken of as a probable successor to his office of President of the Royal Society, Davies Gilbert, however, being chosen. He died in 1829, at the age of 56, and his character was thus drawn by his intimate friend Sir Humphry Davy:—"A man of universal erudition and almost universal accomplishments. Had he limited himself to any one department of knowledge, he must have been first in that department. But as a mathematician, a scholar, and a hieroglyphist, he was eminent; and he knew so much that it was difficult to say what he did not know."

Sir Humphry Davy's brilliant career, and especially that portion of it which contributed so greatly to the fame and success of the Institution with which he was connected, is drawn in detail by his biographer; and the failings in his character and in his life which obscured its lustre to his contemporaries are in no way concealed. The following contrast of the characters of Davy and of his pupil and successor, Faraday, will be read with interest:—"Whenever a true comparison between these two nobles of the Institution can be made, it will probably be seen that the genius of Davy has been hid by the perfection of Faraday. Incomparably superior as Faraday was in unselfishness, exactness, and perseverance, and in many other respects also, yet certainly in originality and in eloquence he was inferior to Davy, and in love of research he was by no means his superior." As early as 1804, when Davy was only twenty-six, Dr. Dalton consulted him as to the best mode of preparing his lectures, and described him as "a very agreeable and intelligent young man, the principal failing in whose character as a philosopher is that he does not smoke;" and within two or three years from that time he had made the discoveries which have immortalised his name.

Dr. Bence Jones does not carry down the history of the Royal Institution beyond 1814, when it became as closely associated with Faraday's career as it had previously been with Davy's. We have seen what were the primary objects for the promotion of which the Institution was founded; and we know also the great work which it effected during the first ten years of its existence. These special purposes soon gave way to the effort, as our author expresses it, after striving to be fashionable; and the fashionable element has continued to be the most prominent feature in its subsequent life to the present day. Something is, no doubt, gained by making scientific subjects one of the ordinary topics of conversation in West End salons; the continuation of the History of the Royal Institution, which will have to be written twenty years hence, will show whether this object is compatible with the carrying on of original investigations which will add to the sum of our knowledge of the laws of Nature.

OUR BOOK SHELF

Une Expérience relative à la Question de la Vapeur Vesiculaire. Par M. J. Plateau. (Brussels: F. Hayez.)

THE elder Saussure, and after him De Luc, considered it to be an established fact that clouds are formed of little hollow globules, which Saussure designated vesicular

vapours, or vesicles. These vesicles, having a structure similar to the soap bubble, were assumed to be capable of floating in the atmosphere and of remaining suspended in it so long as their physical condition was unaltered. When they became resolved into drops of water they formed rain. The same structure was assigned to the cloud formed by the condensation of the vapour of boiling water in air colder than itself. M. Plateau has endeavoured to put this view of the vesicular constitution of vapour to the test of experiment. With this view he has taken advantage of a method devised by M. Duprez, for inverting a wide tube (20mm. in diameter) full of water, so that the water may remain suspended in the tube. By means of a narrow tube drawn out at one end, so as to present an orifice of 0.1mm. in diameter, he succeeded in obtaining small hollow globules of water of less than a millimetre in diameter, and transporting them under the free surface of the water, suspended in the wide tube. As soon as contact was established with that surface, the little bubble became detached, and the air which it contained penetrating into the liquid, mounted through it. The experiment, on being several times repeated, gave always the same result. M. Plateau has applied this method to the cloud formed when water is boiled in free air. "Let us imagine," he says, "that at a certain distance from the surface of the water suspended in the wide tube, a current of visible vapour of water arises. If this vapour is composed of vesicles, each of them which comes into contact with the liquid surface must introduce into the water a microscopic bubble of air, which will immediately begin to ascend, so that the whole will form in the water of the tube a cloud which will rise slowly in it, and alter its transparency." In making the experiment, no cloud was produced, and M. Plateau concludes, in conformity with the view now generally held by physicists, that the vesicular state of vapour has no real existence. He discusses objections which may be raised to his experiment, such as the possible solution of the bubbles of air in the water, the bursting of the bubbles at the surface of the water and the escape of the air contained in them, or their rolling under the surface of the water till they reach the margin of the tube and thus get away; and shows satisfactorily that these objections do not invalidate the result at which he has arrived.

Chemical Notes for the Lecture Room, on Heat, Laws of Chemical Combination, and Chemistry of non-Metallic Elements. By Thomas Wood, Ph.D., F.C.S. Pp. 181. (London: Longmans, Green, and Co.)

ON reading this volume the author's intention is plainly manifest; the book has been written principally for the use of students preparing for the matriculation examination at the University of London. It has been written as concisely as possible, rendering the task of "cramming" the subject more easy of attainment. For such a purpose we certainly can recommend this book; but for beginners who wish to study chemistry we think it has several faults. One of them is that such a comparatively large amount of the book is devoted to the subsidiary subject, Heat, almost a quarter of the text being thus occupied. The article on thermometers, for instance, occupies no less than nine pages, which strikes us as being rather out of proportion to the remainder of the book. A second fault is the almost complete absence of any such details as would enable a student to repeat the experiments mentioned in the text. This we think is a fault which would tend to make the beginner get up his subject parrot-like, a method which is certainly not to be desired. The chemistry of the non-metallic elements only occupies eighty-five pages of this volume; the definitions and laws of chemical combination occupy another thirty-eight pages. The explanations, in the majority of instances, are clearly expressed, the facts of the case being stated in as few words as possible. A few of the definitions can scarcely be considered good; one, in particular, is "that

a compound of any non-metal with a metal is a salt of a metal." This would, of course, include such bodies as antimonetted and arsenetted hydrogen, hydride of copper, and so on. The definitions of acids and bases, too, are weak. It may almost be inferred that such is the case, by the manner in which the author uses the term acid; N_2O_3 is called nitrous acid; I_2O_5 iodic acid, and, in the same line, $HBrO_3$ bromic acid; B_2O_3 boracic acid, and so on. There is one thing which the author tells us which is a curiosity in chemical history. On page 38 it is stated "some few of the elements receive their symbols from the names given to them by the ancients—e.g. Iron (Fe.) from *Ferrum*, Sodium (Na.) from *Natrium*." We certainly were under the impression that Sodium was discovered in 1807 by Sir Humphry Davy. A number of questions are appended to the book which will be found very useful to those employed in teaching.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

Ocean Currents

SURELY Mr. Ferrel must have misapprehended my arguments, or he would not have advanced the case of the tides against me. Undoubtedly the ocean will sink to its old level when the lifting force of the moon is withdrawn, even though the height to which the waters are raised may not exceed an inch. I agree also with what he says in regard to the improbability of ocean currents being caused by the heaping up of the waters by the winds. I believe that this erroneous view of the matter has done more real mischief to the wind theory than all the arguments advanced by the advocates of the gravitation theory put together. The notion that because the winds are applied to the surface of the ocean they can produce only surface drift is an error of a similar character.

I shall shortly refer to an important point bearing on the influence of rotation overlooked both by Dr. Colding and Mr. Ferrel. In my last paper in the *Phil. Mag.*, October 1871, p. 266, there is a trifling mistake to which I shall also refer.

Edinburgh

JAMES CROLL

Science Stations

ALLOW me to say a few words in reply to your editorial of Feb. 29. It does seem to me to be a pity to "run the risk of spoiling a good work" by multiplying suggestions and urging counter claims. It is not quite fair that when biologists start a proposal for obtaining a necessary but costly aid to their studies, the devotees of other sciences should exclaim, "Oh, we must have one, too!" If all speak at once in this way no one will be heard, and we shall get no stations of any sort. Probably the writer of the article is not aware of the expense and requirements of a zoological station, otherwise he would not propose to increase the difficulty by thrusting a meteorological and astronomical observatory on the backs of its promoters, and then observe that "the outlay need not be heavy." It is notorious that there are meteorological and astronomical observatories in almost every part of the globe; but there is nothing of the kind for zoology. Under these circumstances it is to me a disappointment that the suggestion for zoological stations meets with what looks like a somewhat selfish criticism, in place of unqualified support, at the hands of physicists.

As to the station in England, I do not gather from Dr. Dohrn's article that he proposes to separate teaching entirely, or even partially, from the stations. He leaves it alone. "Teaching" can come or go just as those who deal in it may please; but that instruction in rudimentary zoology should be a chief object of the station is a proposal of the same nature as would be that to make use of Greenwich Observatory for giving lessons in the outlines of astronomy, and is not entertained by him for a moment. It no doubt would be a very good thing that students from Cambridge and Oxford and London should spend some time in a zoological station; and it would also be good for others of them to work in a lead or copper mine, or pass a few nights

in an astronomical observatory; but we cannot urge the wants of these particular students as any reason for the maintenance of these three things. The primary object for which zoological stations will be erected—one for which it is to be hoped that the Universities, as well as scientific societies and private individuals, will be ready to subscribe money—is the prosecution of science.

We claim for biology now a place of far higher importance in the scheme of human knowledge than she has occupied hitherto. She has proved her claim to the respect and most serious attention of men by the discovery of the principles and detailed laws of evolution—a discovery which has more widely influenced human thought than has any other product of modern science, and must continue long so to do. We are no longer content to see biology scoffed at as "inexact," or gently dropped as "natural history," or praised for her relations to medicine. On the contrary, biology is the science whose development belongs to the day. At this moment she is deserving of more attention, more material aid, more assistance in her young growth, than any other human science. Her youthful performances, her hopeful stride onward, promise more abundant results from pecuniary aid given to her than can be hoped for from her older sisters, who have "settled in life." If biology requires "stations," she ought to be gladly supplied with them.

I must protest against the notion—urged in your article only, I imagine, as a joke—that without "teaching" (whatever that may mean) there would be danger of a zoological station becoming the home of a narrow zoological clique. The connection is not explained, and I do not think any of your readers will see it. Are observatories the homes of narrow astronomical cliques? Are telescopes without professors liable to become the resort of ambitious young persons, anxious chiefly to discover hydrogen flames where nobody had found them before? I do not believe a bit in the narrow clique suggestion. Teaching bodies breed them much more rapidly and naturally than do working bodies. And as to the privat-docent, anxious to discover a note-chord, or the amateur astronomer hunting for hydrogen flames, I would most gladly see them multiplied exceeding abundantly. Would that we could obtain the insitution of "privat-docents" in English Universities; by simply erecting a zoological station, would that we could infuse some of their kind of ambition—one of the best a man can have—into English students.

Naples, March 4

E. RAY LANKESTER

[*.* The article to which our correspondent refers was written by a distinguished biologist.—ED.]

The Etymology of "Whin."

THE following is from Jamieson:—"Quhyn, Quhin-Stane, s. i. Green-stone; the name given to basalt, trap, &c. . . . Isl. *hwiyna*, resonare, *hwin*, resonans, q. 'the resounding stone.'" "Whin, whinstane, s. Ragstone or toadstone."

Whin or gorse, the name given to *Ulex eurobeus*, common furze, is from a different root, being traced to Welsh *chwynyn* = weed.

A. HALL

YOUR correspondent, Mr. W. R. Bell, will find a derivation given for "Whin" in Jamieson's "Scottish Dictionary," where, under the name *Quhyn* or *Quhin*, it is referred to the "I-landic *hwiyna*, resonare," "*hwin*, resonans, q. the resounding stone," probably from the resonance emitted on its being struck. It is in all likelihood the same as the word *whine*, and the root is present in both Celtic and Teutonic tongues, e.g.:

Welsh	<i>Cwyno</i> , to complain
Irish	<i>Cuinead</i> , mourning (?)
Islandic	<i>hwiyna</i> (as above)
Danish	<i>hvine</i> , to whistle
German	<i>weinen</i> , to weep

Compare also the Latin *lunio*, to neigh.

F. DE CHAUMONT

Oakland, Woolston, March 15

WEBSTER, in his Dictionary (9th edition, 1862), says in explaining this word, which is known all over England, that it means *weeds, gorse, furze, waste growth*, from the Welsh *Cwynn*. That it is "a provincial name given to basaltic rock, and applied by miners to any kind of dark coloured and hard unstratified rock which resists the pick."

There is also "*whin-axe*," an instrument for extirpating whin from land.

The Scotch form of whin is *quhyn*.

JOHN JEREMIAH

The Aurora of February 4

THIS Aurora was seen throughout Europe, including Russia and Constantinople, in Egypt, in the Mauritius, and in India.

May not all auroras pervade the atmosphere around the entire globe and be visible wherever night prevails with a sufficiently clear sky? And so may not the southern and northern aurora belong to one and the same universal aurora?

GEORGE GREENWOOD

Alresford, March 16

I SEE notices in the English papers of a great aurora seen in all parts of Scotland, England, and even as far south as Alexandria in Africa. It may be interesting for your readers to know that it was visible here on the same evening—Sunday, February 4. I saw it first at 6.30 P.M., and at various times after that until 10.30, after which I did not look out of doors. There were no streamers, and the peculiarity of the appearance was that it was in all directions, and less in the north than in the west and east. It presented the appearance of a dull red fog, in shifting masses, and more like the haze I observed here in 1867, when the earth was said to have passed through the tail of the comet of that year. Auroras are very rare in this latitude, but we have had four or five displays in fifteen months: one so bright as to excite the alarm of fire, and to call out the fire department.

Barometric Depressions

By the introduction of parenthetical sentences between words, which do to some extent represent my meaning, though they are not mine, as the inverted commas would imply, and by the omission of the main point of his own argument, Mr. Ley has presented as mine certain propositions which may well appear to him and to every one who reads them, not only irreconcilable, but sheer nonsense. As these parenthetical interpolations are Mr. Ley's own, and as the point in his argument to which I took exception was not the application of Buys Ballot's Law, but his proposition—shortly stated—that revolving storms are caused by heavy rain, I conceive that his version of my views, which may be funny but is certainly incorrect, is scarcely worth the serious attention of any one.

As to the rest, it is a great thing, in any branch of science, to establish points beyond the reach of further argument or doubt. The depression of the barometer in summer over a great part of Asia has hitherto seemed one of the most curious and difficult problems in Physical Geography. We now know all about it. There is no more room for doubt. It is "really due" to the rarefaction of the air. Mr. Ley says so. What, how, why, when, or where, are details far too commonplace for him to enter upon.

The whole subject of barometric changes, and their relation to strong winds or storms, is one of extreme difficulty; and, in the present state of our knowledge, we can do little more than guess at or discuss the probable solution of the many questions that arise out of it. From the off-hand way in which Mr. Ley disposes of them, or wishes them disposed of, it would appear that he has not yet arrived at even an appreciation of their difficulty. This is the real point on which we are at issue; the range of his study has been too confined. A more general application of his industry will, I hope—should he again meet me in my capacity of critic—relieve me of the necessity of making remarks unpleasant for him to read, or for me to write.

J. K. L.

The Meteor of March 4

I HAVE been looking out for some corresponding notice of a meteor seen here on March 4, but hitherto in vain. At first I hoped that the interesting accounts from Ireland, published in the last number of *NATURE*, might have referred to the same phenomenon; but I soon found that the dates were discordant,

and I now beg to forward the following brief notice of the earlier one:—

On the above-mentioned evening, about 7h. 40m. P.M. railway time, a brilliant meteor was noticed by my gardener Thomas Wood. According to his account it appeared about 20° or 30° above the N. horizon as a ball of red fire passing rapidly from W. to E., about one-third as large as the full moon, with a tail seven or eight times its diameter in length, the portion nearest the head being reddish; but changing at about one-third of its length to green, which was especially distinct towards its tapering point. The head seemed to be surrounded by some sparks. It threw such a light upon the ground as to show all the growing wheat in the field through which the spectator was passing. The course was rather descending, and it went out suddenly without coming down to the horizon. I have heard of only one other person in the neighbourhood who saw the light cast by the meteor, and who described it as extremely brilliant. It is singular that it has not been more generally noticed. The especial interest attached to it is the fact that, in common with the one observed only four days later in Ireland, its course was in the unusual direction of the earth's motion.

Hardwick Vicarage, Hay, March 18

T. W. WEBB

THEODOR GOLDSTÜCKER

FOR the following particulars of the career of the late Prof. Goldstücker we are indebted mainly to the *Academy and Trübner's Oriental Record*:—

By the death of Theodor Goldstücker, at the early age of fifty-one, philology has lost one of its greatest scholars, and society, what it can still less afford to lose, one of the noblest and most disinterested of men. Born at Königsberg, in Prussia, he began the study of Sanskrit, for the profound knowledge of which he has since become so famous throughout the world, under Prof. Peter von Bohnen, at the University of that town. He continued this study under Profs. August Wilhelm von Schlegel and Christian Lassen at Bonn. He afterwards resided for some time at Paris, where he enjoyed the friendship of men of the greatest distinction, such as Burnouf, Letronne, &c. He then resided at the University of Berlin, where he began soon to display great scholarly activity. Alexander von Humboldt formed already at that time a very high estimate of the capacities of the young scholar, whose aid, in several very difficult questions of Indian philosophy, he gratefully acknowledged in his "*Kosmos*."

After the reaction of 1848-9, Goldstücker came over to England for the purpose of assisting Prof. Wilson in the preparation of a new edition of his Sanskrit Dictionary. For this new edition no material whatever existed save the dictionary itself in its printed form. Goldstücker, nevertheless, undertook its revision single-handed; and the immense proportions which under his hand the first six parts assumed (480 pp. without getting to the end of the first letter) rendered the completion of the work by one man or in one generation impossible. Many thousands of notes and references for this and other works, the result of an unremitting study of the MSS. treasures at the India House, &c., are left behind; and we are glad to learn from the *Academy* that the report in some of the newspapers that the deceased had left directions in his will for their destruction is without foundation.

The earliest work undertaken by Goldstücker was the translation into German of the "*Prabodha Chandrodaya*," a theologic-philosophical drama, by Krischna Micra, to which Professor Rosenkranz wrote a Preface. In 1861 he published, as an Introduction to a Fac-simile Edition of the "*Manava-Kalpa-Sutra*," an investigation of some literary and chronological questions, which may be settled by a study of Panini's work, under the title of "*Panini*, his place in Sanskrit literature." Goldstücker also edited the text of the "*Jaiminiya-nyāya-māla-vistara*," of which work 400 pages in large quarto are in type.

For the last two years he has been engaged in carrying through the press, for the Indian Government, a photographic edition of the "Mahābhāṣya," of which 300 pages still remain to be done. By his decease, what may be called the "traditional" school of Vedic criticism, which gives to the interpretations of native tradition the preference over those derived from comparative philology, ceases to have a European representative. His manuscript of a Sanskrit grammar has long been finished, and it is hoped that this work, which is likely to revolutionise the teaching of Sanskrit in many respects, may be allowed to see the light. The great psychological value as an educational instrument which he attached to the Sanskrit language, if properly taught, was well known to his friends; and it was through his advocacy that a committee of the professors of University College, London, was appointed to report on the desirableness of making Sanskrit an integral part of all the degree examinations in the University of London.

Of the philosophical literature of India, the "Mīmāṃsā," from its close connection with grammatical researches, engaged his chief attention; some fruit of his labours in this field is a nearly finished edition, prepared for the Sanskrit Society, of Mādhava's "Jaiminiya-nyāya-mālavistara" (1865).

It was however Goldstücker's thorough familiarity with the legal and ceremonial literature of the Hindus which rendered his advice of so much value to the Indian Government. A paper recently published by him "On the Deficiencies in the Present Administration of Hindu Law" (Trübner, 1871), contains an exposure of the frequent failures of justice arising from the misunderstandings of native codes, which disgrace our Indian administration.

Besides some papers in the *Reader* and the *Athenæum*, Goldstücker contributed an excellent essay on the "Mahābhārata" to the *Westminster Review* in April 1868; and among his papers will be found a copy of the great Eastern epic collated with the best European MSS. His library is, we are glad to hear, to be kept together.

Dr. Goldstücker was Professor of Sanskrit in University College, London, President of the Philological Society, a member of the Council of the Asiatic Society and of the Association of the Friends of India.

REPORT OF THE ASSOCIATION FOR THE IMPROVEMENT OF GEOMETRICAL TEACHING

AT the Second Annual Meeting of this Association, held at University College, London, on January 12, Dr. Hirst, the president of the association, delivered the following address:—

In opening the proceedings of this, the Second Annual Meeting of the Association for the Improvement of Geometrical Teaching, I am glad to be able to congratulate you on the decided progress which has been made during the past year towards the realisation of your views. The discussions recorded in English journals, and the reception given to recently published text-books on geometry, unquestionably indicate that public opinion is far more inclined now than it was a few years ago to entertain the notion of an improved exposition of the elements of geometry. We are no longer warned that to touch that edition of Euclid to which, for more than a century, we have paid such literal homage, would be to ruin the teaching of geometry. On the contrary, it is now generally admitted that, without departing from the admirable exactitude and geometrical purity of Euclid's elements, we ought to be able, by judicious revision and extension, to bring them more into harmony with the scientific methods and the habits of thought of our own day. I alluded last year to the retrograde step that had been taken in Italy

on this question of the teaching of geometry. The announcement excited much interest in England, though the true purport of the Italian movement was, I fear, slightly misunderstood. I have, therefore, thought it my duty to procure original documents, to make inquiries into the success of the Italian movement of 1867, and also to ascertain the present aspect of geometrical instruction in that country. I hold in my hand the historically interesting document which was issued by the Italian Government in 1871. It contains instructions and programmes relative to the teaching of mathematics in their *Ginnasi* and *Licei*.* Before quoting it I may observe that the *Ginnasio* is essentially a classical school, mathematics being studied only in its fifth or highest class, and then only for five hours a week; and that in the *Liceo* the instruction is still to a great extent classical, though less exclusively so. Here, as the pupil advances through its three classes, mathematics, physics, natural history, and philosophy become more and more prominent as subjects of study. The instructions, as already observed, relate solely to the teaching of mathematics in these classical schools; nevertheless, the following introductory remarks on the objects of mathematical study are, I venture to think, applicable to all schools in which the foundation of a truly liberal education is to be secured: "Mathematics should not be looked upon as a mere collection of intrinsically useful propositions or theorems of which boys ought to acquire a knowledge in order to be able to apply them subsequently to the practical purposes of life. The study should be regarded principally as a means of intellectual culture, directed towards the development of the faculty of reasoning, and to the strengthening of that just and healthy judgment which serves as the light whereby we distinguish truth from that which has but the semblance thereof."

After describing the course of instruction in arithmetic and algebra best suited to the end in view, the document before me proceeds thus:—"In order to give to the instruction in geometry its maximum intellectual efficacy, and at the same time to bring the subject-matter within reasonable limits, it will suffice to follow, in our schools, the example of English ones by returning to the elements of Euclid, universally admitted to be the most perfect model of geometrical rigour." It would be a grave error to suppose that it was the good results on geometrical teaching of our adherence to the elements of Euclid that induced the Italians to return to them. Although England is made, in some measure, responsible for the step taken, we know from sources alluded to in my address last year that the main object in taking it was to purge from Italian schools the many worthless books which private enterprise had succeeded in introducing, and by no other means than the one adopted could the Italian Government, in the opinion of their advisers, have achieved this end with sufficient promptitude and impartiality.

The real motive of the order issued in 1867 is a little more apparent in the following passage from the Instructions, wherein allusion is made to the practice, then prevalent, of striving after a deceptive facility of treatment by the introduction of algebraical processes in place of geometrical reasoning: "The instruction in geometry is to extend to the first six, and to the eleventh and twelfth, books of Euclid, and to be followed by lessons on the most essential propositions of Archimedes relating to the measure of the circle, of the cylinder, of the cone, and of the sphere. Taught by the method of the ancients, geometry is easier and more attractive than the abstract science of number; hence, instead of postponing geometry to algebra, one part of the subject (the first book) is assigned to the fifth class in the *Ginnasio*, and another (the second and third book) to the first class of the *Liceo*. The teacher is recommended to adhere to the method of

* Istruzione e Programmi, per l'Insegnamento della Matematica nei Ginnasi e nei Licei, approvati con R. Decreto, 10 Ottobre, 1867.

Euclid, as the one best fitted to establish in the youthful mind the habit of thoroughly rigorous reasoning; above all, he is not to impair the purity of the ancient geometry by transforming geometrical theorems into algebraic formulæ, that is to say, by substituting in place of concrete magnitude—such as lines, angles, superficies, volumes—their respective measures; on the contrary he is to accustom his pupils to reason always on the magnitudes themselves even when their ratios are under contemplation. It is only after the propositions of Euclid and of Archimedes, mentioned in the programme, have been mastered that formulæ are to be deduced for practically determining the areas of rectilinear figures, the area of the circle, the length of its circumference, and the magnitudes of the surfaces and volumes of prisms, pyramids, cylinders, cones, and spheres."

The measures taken by the Italian Government in 1867 have, I am informed, fully answered the expectations of the mathematicians who recommended them. A taste for rigorous and purely geometrical methods has been revived, and the ground has been cleared for further advances. That such advances were contemplated from the first is obvious from the following passages, with which the Professors Betti and Brioschi—two of the most distinguished mathematicians of Italy—concluded their preface to the new edition (based on that of Viviani) of the Elements of Euclid, with which classical schools were supplied in 1867:—"Profoundly convinced that it is only through the eminent qualities of precision and clearness which distinguished Euclid's Geometry that we can hope, in seeking to promote the intellectual development of our youth, to secure those results at which all civilised nations aim when they give to geometrical instruction so important a place in public instruction, we have undertaken the publication of an edition of the elements with the fixed intention of improving it whenever new foreign publications and the experience gained in our own schools shall have shown that improvements are desirable. We trust that professors in *Licei* will help us in this work. We shall gratefully accept their observations and suggestions."

Experience, however, has gone further than was here anticipated; already there appears to be a demand for something beyond a revision of Viviani's edition of Euclid's Elements. In the *Gazzetta Ufficiale* of the kingdom of Italy, published at Rome, I find that on the 2nd of December last an announcement was made by the authority of the Minister of Public Instruction, to the effect that in 1873 a prize of 2,500 lire (about 100*l*) would be given to the author of the best "Treatise on Elementary Geometry which shall adhere rigorously to the method of Euclid, and contain, besides the subject-matter in the programme of 1867, those portions of the science, developed since Euclid's time, which are now to be found in all elements of geometry adopted as text-books in the classical schools of the most cultured nations." I forbear to attempt to determine what would be the rank of England amongst cultured nations if she were judged by this standard of the introduction of post-Euclidean matter into school text-books. I prefer to see in the announcement merely an encouragement to proceed with our self-imposed task of endeavouring to bring up the teaching of geometry and the text-book we employ to the level of the science of our day. In Italy this can be done more promptly than in England. Our Government cannot, with a stroke of the pen, alter the entire character of the instruction given in English schools. With us improvements are of slower growth, and it is by operations less surgical in their character that obstructions to their growth have first to be removed. It is, in fact, the function of associations like our own to endeavour to remove unreasonable prejudices against changes in the English habit of teaching geometry by bringing prominently forward the defects which we find to exist, and the improvements which we desire to

see introduced. Let me now turn, therefore, to the work done by this association during the past year. You will recollect that members were invited to prepare programmes and syllabuses of text-books on geometry in accordance with their own views. The primary object in making this request was to ascertain what amount of unanimity at present prevails amongst teachers. The invitation was accepted by many, and the syllabuses received were referred to two committees, one meeting at London and the other at Rugby. Although the occupations of many of us, and our distances asunder, rendered it very difficult to secure concerted action, a report has at length been prepared, and will be this day submitted to you. With respect to the resolutions and recommendations embodied in this report, I will for the present confine myself to the statement that the main object they are intended to further is a practically useful degree of conformity amongst teachers during the present transitional state of matters. No attempt has been made to prepare any detailed scheme or programme of elementary geometrical study. This last difficult task, however, although postponed, is not, as you will hereafter see, abandoned.

Although the assertion may partake of the character of a truism, it cannot be too often insisted upon, that however necessary it may be to have good text-books, it is far more necessary to have good teachers; that, in fact, good text-books are useful principally by the aid they render in forming good teachers and in furnishing students with an accurate record of what they have been taught. In teaching, one might say, there is *vis viva*—actual energy; whereas in a text-book, however good it may be, the disciplinary energy is at most potential. The text-book, indeed, to be properly used, should always be subordinated to the teaching; but to do this it is absolutely essential that the teacher should, by his own study, have risen not merely up to, but above, the level of the text-book he employs. Until he has so mastered the subject that it has become plastic in his hands, his teaching must necessarily remain defective; for geometrical truth, it must be remembered, has, like all other truth, many sides, and no text-book can present all, or necessarily the one which, to individual pupils, is the most accessible. Alternative methods of demonstration, inquiries into the interdependence of propositions, judicious variation of data, and just discrimination between the contingent and necessary properties of figures; these and numerous other matters, all essential to geometrical culture, can only be properly supplied by the teacher; no text-book could be weighted with them. Above all, it is to him that we must mainly look for the cultivation of that scientific method of inquiry under whose guidance solely problem-solving can be raised in character above what has been termed "exalted conundrum guessing," and acquire its full educational value.

The interdependence of geometrical propositions above alluded to, as one of the subjects to which teachers should habitually direct the attention of their pupils, is mainly logical in character, but nevertheless most essential to geometrical culture. Every one will admit the primary importance of habituating the student to extract its full logical significance from every proposition he establishes, to recognise each proposition readily under different, although logically equivalent forms of enunciation, and thus to discriminate accurately between the cases where mere logical deduction from antecedent propositions is requisite, from those which require the introduction of further geometrical considerations. Obvious as this may be, it is rarely sufficiently attended to by teachers, and even in approved text-books, ancient as well as modern, we not unfrequently find remarkable instances of the absence of the discrimination to which I refer. The ninth proposition of the third book of Euclid is now a well-known case of the kind. Geometrical apparatus is there employed to demonstrate, indirectly, what had virtually

been already proved in the seventh proposition. Having proved that *from a point which is not the centre three equal straight lines cannot be drawn to the circumference of a circle* (Prop. 7), it was wholly unnecessary to prove that *the point from which three equal straight lines can be drawn to the circumference must be the centre of the circle* (Prop. 9).

The two theorems are, in fact, contra-positive forms, one of the other; the truth of each is implied, when that of the other is asserted, and to demonstrate both geometrically is more than superfluous; it is a mistake, since the true relation between the two is thereby masked. There can be no better proof of this than the fact that the above defect in exposition remained undetected for centuries. Another, though less striking, example of the same kind is presented by the 16th and 27th propositions of the first book. Few intelligent boys fail on first reading the 27th to note the oddity of giving to two parallel lines a dagger-like shape in order to prove indirectly that "if a straight line falling on two other straight lines make the alternate angles equal to each other, these two straight lines shall be parallel." It is certain, however, that few of them ever discover that the proposition has virtually been proved before, that it is in fact the contra-positive form of the 16th, since the latter is obviously susceptible of being thus enunciated: "If two straight lines meet one another, a straight line falling on them will not make the alternate angles equal."

The late Prof. de Morgan, to whose keen penetration we owe the detection, not merely of the above defects in Euclid, but of many others, strongly and justly insisted upon the necessity of a more logical study of the elements of geometry.

I do not advocate the introduction of more *formal* logic into elementary geometry, but simply the cultivation of a logically severer habit of thought, and the more frequent application of these simple rules of reasoning by means of which tedious reiteration may be so often obviated, and, as a consequence, clearness of insight promoted. As an instance of such a rule I may mention that very useful one according to which "the converse of each of a series of demonstrated theorems is necessarily true if of their several hypotheses, as well as of their predicates, it can be said that one must be true, and that no two of them can be so at the same time." A conviction of the general validity of this rule is readily imparted, even to your pupils, by first selecting familiar instances and then generalising; and, once imparted, they are put in possession of the instrument whereby converse propositions in geometry are most frequently and satisfactorily established.

In conclusion, I may observe that it is chiefly by the aid of general rules, such as those just alluded to, that the mechanical details of demonstration become sufficiently subordinated to allow a complete grasp of the whole subject to be acquired; they serve, in fact, as the thread on which the isolated propositions of geometry, like beads, have to be strung before they can be properly viewed.

THE YELLOWSTONE PARK

THE following, reprinted from the "Reports to Congress" of the United States, will serve to show the zeal displayed by the American Government for the improvement of the people. We regret that we are unable to reproduce the accompanying maps:—

"The Bill now before Congress has for its object the withdrawal from settlement, occupancy, or sale, under the laws of the United States, a tract of land fifty-five by sixty-five miles, about the sources of the Yellowstone and Missouri Rivers; and dedicates and sets it apart as a great national park or pleasure-ground for the benefit

and enjoyment of the people. The entire area comprised within the limits of the reservation contemplated in this Bill is not susceptible of cultivation with any degree of certainty, and the winters would be too severe for stock-raising. Whenever the altitude of the mountain districts exceed 6,000ft. above tide-water, their settlement becomes problematical unless there are valuable mines to attract people. The entire area within the limits of the proposed reservation is over 6,000ft. in altitude, and the Yellowstone Lake, which occupies an area 15 miles by 22 miles, or 330 square miles, is 7,427ft. The ranges of mountains that hem the valleys in on every side rise to the height of 10,000ft. and 12,000ft. and are covered with snow all the year. These mountains are all of volcanic origin, and it is not probable that any mines or minerals of value will ever be found there. During the months of June, July, and August, the climate is pure and most invigorating, with scarcely any rain or storms of any kind; but the thermometer frequently sinks as low as 26°. There is frost every month of the year. This whole region was in comparatively modern geological times the scene of the most wonderful volcanic activity of any portion of our country. The hot springs and the geysers represent the last stages—the vents or escape-pipes—of these remarkable volcanic manifestations of the internal forces. All these springs are adorned with decorations more beautiful than human art ever conceived, and which have required thousands of years for the cunning hand of nature to form. Persons are now waiting for the spring to open to enter in and take possession of these remarkable curiosities, to make merchandise of these beautiful specimens, to fence in those rare wonders so as to charge visitors a fee, as is now done at Niagara Falls, for the sight of that which ought to be as free as the air or water.

"In a few years this region will be a place of resort for all classes of people from all portions of the world. The geysers of Iceland, which have been objects of interest for the scientific men and travellers of the entire world, sink into insignificance in comparison with the hot springs of the Yellowstone and Fire-Hole Basins. As a place of resort for invalids it will not be excelled by any portion of the world. If this Bill fails to become a law this session, the Vandals who are now waiting to enter into this wonderland will, in a single season, despoil beyond recovery these remarkable curiosities which have required all the cunning skill of nature thousands of years to prepare.

"We have already shown that no portion of this tract can ever be made available for agricultural or mining purposes. Even if the altitude and the climate would permit the country to be made available, not over fifty square miles of the entire area could be settled. The valleys are all narrow, hemmed in by high volcanic mountains like gigantic walls.

"The withdrawal of this tract, therefore, from sale or settlement takes nothing from the value of the public domain, and is no pecuniary loss to the Government, but will be regarded by the entire civilised world as a step of progress and an honour to Congress and the nation.

Department of the Interior,
Washington, D. C., January 29, 1872

Sir,—I have the honour to acknowledge the receipt of your communication of the 27th instant relative to the Bill now pending in the House of Representatives dedicating that tract of country known as the Yellowstone Valley as a national park.

I hand you herewith the report of Dr. F. V. Hayden, United States geologist, relative to said proposed reservation, and have only to add that I fully concur in his recommendations, and trust that the Bill referred to may speedily become a law.

Very respectfully, your obedient servant,
C. DELANO, Secretary.

Hon. M. H. Dunnell, House of Representatives.

"The committee therefore recommend the passage of the bill without amendment."

DR. LIEBREICH ON TURNER AND
MULREADY

DR. R. LIEBREICH, in a lecture delivered at the Royal Institution on Friday, the 8th inst., "On the effects of certain faults of vision on painting, with special reference to Turner and Mulready," successfully vindicated the title of physical science to extend its researches into the domain of art criticism by applying optical laws to painting. The lecture may be said to consist of three parts, the first of which demonstrates, by the example of Turner, that there are certain conditions of the eye which alter the appearance of nature, whilst they leave the impression a picture produces upon the eye unchanged. The second part of the lecture proves, by the example of a French artist yet living, whose name, therefore, was withheld, that there is another defect of the eye, which produces an incorrect impression of the picture as well as of nature, the error, however, being dissimilar, and affecting the picture and nature in opposite ways. The third part of the lecture shows, by the example of Mulready, that there is yet another disease of the eye affecting colours in such a manner that pigments used in painting are influenced by the disease, whilst natural colours continue unaltered.

I.—TURNER

Surprised at the great difference between Turner's earlier and later works, said the lecturer, he examined one of the great artist's later pictures from a purely scientific point of view, and analysed it with regard to colour, drawing, and distribution of light and shade.

It was particularly important to ascertain if the anomaly of the whole picture could be deduced from a regularly recurring fault in its details. This fault is a vertical streakiness, which is caused by every illuminated point having been changed into a vertical line. The elongation is, generally speaking, in exact proportion to the brightness of the light; that is to say, the more intense the light which diffuses itself from the illuminated point in nature, the longer becomes the line which represents it on the picture. Thus, for instance, there proceeds from the sun in the centre of a picture a vertical yellow streak, dividing it into two entirely distinct halves, which are not connected by any horizontal line. In Turner's earlier pictures the disc of the sun is clearly defined, the light equally radiating to all parts; and even where, through the reflection of water, a vertical streak is produced, there appears, distinctly marked through the vertical streak of light, the line of the horizon, the demarcation of the land in the foreground, and the outline of the waves in a horizontal direction. In the pictures, however, of which I am now speaking (the lecturer proceeded to say), the tracing of any detail is perfectly effaced when it falls in the vertical streak of light. Even less illuminated objects, like houses or figures, form considerably elongated streaks of light. In this manner, therefore, houses that stand near the water, or people in a boat, blend so entirely with the reflection in the water, that the horizontal line of demarcation between house and water or boat and water entirely disappears, and all becomes a conglomeration of vertical lines. Everything that is abnormal in the shape of objects, in the drawing, and even in the colouring of the pictures of this period, can be explained by this vertical diffusion of light.

How and at what time did this anomaly develop itself?

Till the year 1830 all is normal. In 1831 a change in the colouring becomes for the first time perceptible, which gives to the works of Turner a peculiar character not found in any other master. Optically this is caused by an increased intensity of the diffused light proceeding from the most illuminated parts of the landscape. This light forms a haze of a bluish colour which contrasts too much with the surrounding portion in shadow. From the year 1833 this diffusion of light becomes more and more verti-

cal. It gradually increases during the following years. At first it can only be perceived by a careful examination of the picture; but from the year 1839 the regular vertical streaks become apparent to every one. This increases subsequently to such a degree, that when the pictures are closely examined they appear as if they had been wilfully destroyed by vertical strokes of the brush before they were dry, and it is only from a considerable distance that the object and meaning of the picture can be comprehended. During the last years of Turner's life this peculiarity became so extreme that his pictures can hardly be understood at all.

It is a generally received opinion that Turner adopted a peculiar manner, that he exaggerated it more and more, and that his last works are the result of a deranged intellect. I am convinced of the incorrectness, I might almost say of the injustice, of this opinion. According to my idea, Turner's manner is exclusively the result of a change in his eyes, which developed itself during the last twenty years of his life. In consequence of it the aspect of nature gradually changed for him, while he continued in an unconscious, I might almost say in a naïve manner, to reproduce what he saw. And he reproduced it so faithfully and accurately, that he enables us distinctly to recognise the nature of the disease of his eyes, to follow its development step by step, and to prove by an optical contrivance the correctness of our diagnosis. By the aid of this contrivance we can see nature under the same aspect as he saw and represented it. With the same we can also, as I shall prove to you by an experiment, give to Turner's early pictures the appearance of those of the later period.

After he had reached the age of fifty-five, the crystalline lenses of Turner's eyes became rather dim, and dispersed the light more strongly, and in consequence threw a bluish mist over illuminated objects. In the years that followed, as often happens in such cases, a clearly defined opacity was formed in the slight and diffuse dimness of the crystalline lens. In consequence of this the light was no longer evenly diffused in all directions, but principally dispersed in a vertical direction. At this period the alteration offers, in the case of a painter, the peculiarity that it only affects the appearance of natural objects, where the light is strong enough to produce this disturbing effect, whilst the light of his painting is too feeble to do so: therefore, the aspect of nature is altered, that of his picture correct.

The lecturer proceeded to demonstrate the truth of his remarks by a series of experiments, which showed, for instance, a natural tree, and then, by means of lenses prepared for the purpose, changed it into a "Turner-tree;" likewise the artist's early picture of "Venice" was shown, and, by means of lenses, changed into the "Venice" of Turner's later period.

II.—ASTIGMATISM

The optical state of the eye during its adaptation for the farthest point, when every effort of accommodation is completely suspended, is called its refraction.

There are three different kinds of refraction: firstly, that of the normal eye; secondly, of the short-sighted eye; thirdly, of the over-sighted eye.

1. The normal eye, when the activity of its accommodation is perfectly suspended, is adjusted for the infinite distance; that is to say, it unites upon the retina parallel rays of light. (Fig. 1.)

2. The short-sighted eye has in consequence of an extension of its axis a stronger refraction, and unites, therefore, in front of the retina the rays of light which proceed from infinite distance. In order to be united upon the retina itself the rays of light must be divergent, that is to say, they must come from a nearer point. The more short-sighted the eye is, the stronger must be the divergency; such an eye, in order to see distinctly distant objects, must make the rays from a distant object more divergent, by aid of a concave glass. (Fig. 2.)

3. The over-sighted (hypermetropic) eye, on the contrary, has too weak a refraction; it unites convergent rays of light upon the retina; parallel or divergent rays of light it unites behind the retina, unless an effort of accommodation is made. (Fig. 3.)

Hypermetropy, the lecturer explained, does not essentially influence painting, and is easily corrected by convex glasses. Short-sightedness, on the contrary, generally influences the choice of subject as well as its manner of execution.

Sometimes the shape of the eye diverges from its normal spherical form, and this is called astigmatism. This has only been closely investigated since Airy discovered it in his own eye. Figure to yourself meridians drawn on the eye as on a globe, so that one pole is placed in front; then you can define astigmatism as a difference in the curvature of two meridians, which may, for instance, stand perpendicularly upon each other; the consequence of which is a difference in the power of refraction of the eye in the direction of the two meridians. An eye may, for instance, have a normal refraction in its horizontal meridian, and be short-sighted in its vertical meridian. Small differences of this kind are found in almost every eye, but are not perceived. Higher degrees of astigmatism, which decidedly disturb vision, are, however, not uncommon, and are therefore also found among painters.

I observed a very curious influence of astigmatism upon the works of a portrait painter. He was held in high esteem in Paris, on account of his excellent grasp of character and intellectual individuality. His admirers considered even the material resemblance of his portraits as perfect; most people, however, thought he had intentionally neglected the material likeness by rendering in an indistinct and vague manner the details of the features and the forms. A careful analysis of the picture shows that this indistinctness was not at all intentional, but simply the consequence of astigmatism. Within the last few years the portraits of this painter have become considerably worse, because the former indistinctness has grown into positively false proportions. The neck and oval of the face appear in all his portraits considerably elongated, and all details are in the same manner distorted. What is the cause of this? Has the degree of his astigmatism increased? No; this does not often happen; but the effect of astigmatism has doubled, and this has happened in the following manner:—An eye which is normal as regards the vision of vertical lines, but short-sighted for horizontal lines, sees the objects elongated in a vertical direction. When the time of life arrives that the normal eye becomes far-sighted, but not yet the short-sighted eye, this astigmatic eye will at short distance see the vertical lines indistinctly, but horizontal lines still distinctly, and therefore near objects elongated in a horizontal direction. The portrait painter, in whom a slight degree of astigmatism manifested itself at first only by the indistinctness of the horizontal lines, has now become far-sighted for vertical lines, therefore he sees a distant person elongated in a vertical direction; the portrait he paints, on the contrary, being at a short distance, is seen enlarged in a horizontal direction, and thus painted still more elongated than the subject is seen; so the fault is doubled.

The lecturer proved these remarks by showing a picture which he made to appear in its natural shape or distorted by elongation, in either a vertical or a horizontal direction, by means of a lens which he held at various distances from the optical apparatus.

III.—MULREADY

The lens, continued the lecturer, always gets rather yellow at an advanced age, and with many people the intensity of the discoloration is considerable. This, however does not essentially diminish the power of vision. In

order to get a distinct idea of the effect of this discoloration, it is best to make experiments with yellow glasses of the corresponding shade. Only the experiment must be continued for some time, because at first everything looks yellow to us. But the eye soon gets accustomed to the colour, or rather it becomes dulled with regard to it, and then things appear again in their true light and colour. This is at least the case with all objects of a somewhat bright and deep colour. A more careful examination, however, shows that a pale blue, or rather a certain small quantity of blue, cannot be perceived even after a very prolonged experiment, and after the eye has long got accustomed to the yellow colour, because the yellow glass really excludes it. This must, of course, exercise a considerable influence when looking at pictures, on account of the great difference which necessarily exists between real objects and their representation in pictures.

These differences are many and great, as has been so thoroughly explained by Helmholtz. Let us for a moment waive the consideration of the difference produced by transmitting an object seen as a body upon a simple flat surface, and let us only consider the intensity of light and colour. The intensity of light proceeding from the sun and reflected by objects is so infinitely greater than the strongest light reflected from a picture, that the proportion expressed in numbers is far beyond our comprehension. There is also a great difference between the colour of light or of an illuminated object, and the pigments employed in painting, and it must appear wonderful that the art of painting can produce by the use of them such perfect optical delusions. It can, of course, only produce optical delusions, never a real optical identity; that is to say, the image which is traced in our eye by real objects is not identical with the image produced in our eye by the picture.

Returning to our experiment with the yellow glass, we shall find that it affects our eye very much in the same way as a yellow tint of light. The small quantity of blue light which is excluded by the yellow glass produces no sensible difference, as the difference is equalised by a diminution of sensibility with regard to yellow. In the picture, on the contrary, there is found in many places only as much blue as is perfectly absorbed by the yellow glass, and this therefore can never be perceived, however long we continue the experiment. Even for those parts of the picture which have been painted with the most intense blue the painter could produce, the quantity of blue excluded by the yellow glass will make itself felt, because its power is not so small with regard to pigments as with regard to the blue in nature.

With aged people we often find the crystalline lens to be of a yellowish tint. In pictures painted after the artists were over sixty, therefore, the effect of the yellow lens can often be studied. As a striking example, the lecturer mentioned Mulready. It is generally stated that in his advanced age he painted too purple. A more careful examination shows, however, that the peculiarity of the colours of his later pictures is produced by an addition of blue. Thus, for instance, the shadows on the flesh are painted in pure ultramarine. Blue drapery he painted most unnaturally blue. Red of course became purple. If we look at these pictures through a yellow glass all these faults disappear;—what formerly appeared unnatural and displeasing is at once corrected; the violet colour of the face shows a natural red; the blue shades become grey; the unnatural glaring blue of the drapery is softened. It happens that Mulready has painted the same subject twice, first in the year 1836, when he was fifty years of age and his lens was in a normal state, and again in 1857, when he was seventy-one and the yellow discolouring had already considerably advanced. The first picture was called when exhibited "Brother and Sister; or, Pinching the Ear;" the second was called "The Young Brother." If we look at the

second picture through a yellow glass, the difference between the two almost entirely disappears, as the glass corrects the faults of the picture. The smock of the boy no more appears of that intense blue which we may see in a lady's silk dress, but never in the linen smock of a peasant. It changes into the natural tint we find in the first picture. The purple face of the boy

FIG. 1

also becomes of a natural colour. The shades on the neck of the girl and the arms of the child, which are painted in a pure blue, look now grey, and so do the blue shadows in the clouds. The grey trunk of the tree becomes brown. Surprising is the effect upon the yellowish green foliage, which, instead of appearing still

FIG. 2

more yellow, is restored to its natural colour, and it shows now the same tone of colour as the foliage in the earlier picture. This last fact is most important to prove the correctness of my supposition. The endeavour to explain this fact became for me the starting-point of a series of investigations to ascertain the optical qualities of the pig-

FIG. 3

ments used in painting, and thus to enable us to recognise them by optical contrivances when the vision of the naked eye does not suffice to analyse the colours of a picture.

If it is the dispersion of light which, as in Turner's case, alters the perception of nature, it can be partly rectified by a kind of diaphragm with a small opening (Donder's sthenopeical spectacles).

In cases of astigmatism, the use of cylindrical glasses will completely correct the aspect of nature, as well as of the picture. Certain anomalies in the sensation of colour

may also be counteracted to some extent by the use of coloured glasses; for instance, by a blue glass, when the lens has become yellow, as was the case with Mulready.

If science aims at proving that certain works of art offend against physiological laws, artists and art critics ought not to think that, by being subjected to the material analysis of physiological investigation, that which is noble, beautiful, and purely intellectual would be dragged into the dust. They ought, on the contrary, to make the results of these investigations their own. In this way art critics will often obtain an explanation of the development of the artist, and artists will avoid the inward struggles and disappointments which often arise through the difference between their own perceptions and that of the majority of the public. Never will science be an impediment to creations of genius.

Dr. Liebreich's lecture will appear *in extenso* in the April number of *Macmillan's Magazine*.

THE NATURAL HISTORY OF EASTERN THIBET

DR. CAMPBELL, Superintendent of Darjeeling, has recently published a series of valuable papers on Eastern Thibet in *The Phoenix*, a monthly magazine for China, Japan, and Eastern Asia, ably edited by the Rev. James Summers, Professor of the Chinese Language in King's College. As a journal of this kind must naturally have only a limited circulation, and is not likely to be in the hands of many of our readers, we have no hesitation in abstracting from Dr. Campbell's contributions the following notes on the Zoology and Mineralogy of a country that at the present time is of special interest, both in a geographical and a commercial point of view. The following is a list of the animals of Eastern Thibet, the native name being attached to each:—*Goa*, an antelope; *Gnow*, the *Ovis ammon*; *Rigong*, the hare; *Kiang*, the wild ass; *Lawa*, the musk-deer; *Shao*, a large deer, *Cervus affinis*; *Chen*, *Antelope Hodgsoni*; *Dong*, the wild yak of Thibet; *Pegoo*, the yak; A small cow, whose native name is not given; *Sauk*, cross between cow and yak; *Ba Sauk*, produce of female yak by bull; *Look*, sheep; *Peu Ra*, Thibet goat; *Phak*, the pig; *Cha*, the common fowl; *Danjhar*, the duck; *Danjhar Cheemoo*, the goose (besides the duck and goose there are numerous wild fowls, swimmers and waders, which migrate from India in March, and return in October); *Chungoo*, a reddish wild dog; *Koong*, a mottled civet; *Sik*, the leopard; *Tagh*, the tiger; *Somb*, the bear (a red and a black species); *Nehornehu*, a large sheep, goat, or antelope of various colours, four feet high, with enormous horns four feet long, sloping backwards, and a tail fifteen inches in length.

This completes Dr. Campbell's list of the indigenous mammals and birds. With regard to the *Dong* or wild yak of Thibet, he observes that it is the fiercest of all known ruminants, and will rarely allow a man to escape alive if it can come up with him. It is generally hunted on horseback, the great aim being to detach one from the herd. The horns of the full-grown buck are said to be three feet long, and the circumference must be enormous. They are used by the Grandees at marriage and other feasts as gigantic drinking cups, and handed round to the company. The horns so used are finely polished, and mounted in silver or gold and precious stones. A stuffed "Dong" is common in Thibetan Lamaseras, standing in front of the image of Mahakkali, at whose shrine the animal is thus figuratively sacrificed.

Of *Look* or sheep there are four principal varieties—1st, Chang Look or northern sheep, very large, with fine wool; flocks of from 400 to 1,000 tended by one man. 2nd, Sok Look, rare, but greatly prized; it is a heavy-tailed sheep, coming from the province of Sok, east of Lassa; wool not very fine. 3rd, Lho Look, a very small sheep

indeed, generally white but sometimes black, bred about Lassa; wool very fine and like the shawl wool. 4th. Changumpo Look, abundant about Geroo and in Dingcham, generally very large; the white wool very fine and soft. The flesh of all these sheep is fine-grained and good.

Of the *Phák* or pig there are two varieties, the southern pig, which is similar to the Indian village pig, and the small Chinese pig. There are no wild hogs in Thibet. The Chinese butchers at Lassa blow their pork so as to give it a deceptively fine appearance.

Ducks and geese are not eaten by the Thibetans, but are greatly used by the Chinese, for whom they are specially bred in Lassa.

The lakes of Thibet are full of fish, of which only one kind, named *Choolap*, is described; it grows to the weight of 8lb., and is a coarse food. It is, however, caught and preserved largely; the fish being gutted, split up, the tail put in the mouth, and dried, without salt, in the open air. Thus prepared they will keep for a year. The mode of catching them is singular; when the lakes are frozen over, a hole is made in the ice, to which they rush in such abundance that they are pulled out by the hand.

There are no leeches or mosquitoes in Thibet, nor are maggots or fleas ever seen there; and in Dingcham or Thibet Proper there are no bees or wasps.

Dr. Campbell gives us some very interesting information regarding the food of the Thibetans. During the summer months they use very little fresh meat. They do not like it boiled, and are not partial to it raw, unless it has been dried. In November there is a great slaughter, and a wealthy man, who has perhaps 7,000 sheep, will kill 200 at this time for his year's consumption. The animal after being killed is skinned and gutted and then placed on its feet in a free current of air. In a couple of days it becomes quite hard and is then ready for eating. It is kept in this way for more than a year without spoiling, even during the rainy periods. When long exposed to the wind of Thibet it becomes so dry that it may be rolled into powder between the hands. In this state it is mixed with water and drunk, and used in various other ways. The Thibetans eat animal food in endless forms, and a large portion of the people live on nothing else. The livers of sheep and other animals are similarly dried or frozen, and are much prized, but to strangers they are very distasteful for their bitterness and hardness. The fat is dried, packed in the stomachs, and then sent to market or kept for home use.

With regard to edible vegetables, it is stated that wheat, barley, and buckwheat sown in April or May and irrigated, are reaped in September, barley in Thibet taking the place of potatoes in Ireland, four-fifths of the population living on it. Besides these, the other crops are composed of peas, turnips, and a little mustard. The grain is ground in water mills. The bread is all unleavened, and cooked on heated stoves or gridrons. The sweet pure farinaceous taste of the fine flour equals the best American produce. The staple food of the country is *champa*, called *sultoo* in India; it is finely-ground flour of toasted barley. It is much eaten without further cooking; mixed up with hot tea it is called *paak*; and when prepared with tepid water it is known as *seu*. If any of our readers wish to enter upon "pastures new" in the breakfast department, they may try *Tookpa*, which, to be properly appreciated, should be taken at daybreak before any matutinal ablutions. It is a sort of broth made with mutton, *champa*, dry curds, butter, salt, and turnips.

Goats are also reared in considerable flocks, but for their milk rather than their flesh. The milk of yaks, cows, sheep, and goats is used alike for making dried curds and the various preparations of milk used by these people. Mares' milk is not used in Eastern Thibet.

We now proceed to notice the mineral wealth of this remarkable country.

Pen, a carbonate of soda, is abundant south of the Yaroo; it appears in a whitish powder on the soil, never in masses underground. It is not used for soap-making or otherwise in the arts, but is always put into the water when tea is made, and is much employed medicinally.

Chulla, borax, is only obtained north of the Yaroo, whence it is imported to other parts of Thibet, to India, *viâ* Nepaul, Sikkim, and Bootana, and thence to Calcutta and Europe.

Sicha, saltpetre, is abundantly manufactured in the Cara Thibetan sheep-folds, where composts of sheep's dung and earth are found to produce it.

Lencha, common salt, occurs in commerce in three forms, viz.: *Sercha*, white and best; *Chama*, reddish and good; and *Pencha*, yellowish and bad, containing soda or magnesia and earthy matter. All the salt used in Eastern Thibet is the produce of the lakes and mines north of the Garoo, or comes from Lache, a district between Digarchi and Ladak. According to the best information, all the salt is the produce of lakes, while some assert that it is dug out of the earth. It is certain that the salt-producing districts are all but inaccessible, and can only be traversed by men and sheep; and that their elevation prevents the working from being carried on except in the warmer part of the year, from April to November. Thousands of sheep are employed in carrying the salt to places accessible to yaks, the former animals carrying a load of 20lb. to 24lb. on open places, or of 8lb. to 10lb. in the rugged vicinity of the deposits, whose elevation is not less than 22,000 feet, while the latter are capable of bearing a load of 160lb.

Ser, gold, is found in the sands of a feeder of the Garoo, on its northern side, but the name of the river could not be ascertained by Dr. Campbell. The Garoo itself does not yield any gold washings. Most of the gold of Thibet is the produce of mines or diggings.*

Pabea, the yellow arsenic of commerce, is found west of Lassa, near the borders of China.

There are no mines of iron, silver, copper, quicksilver, lead, or coal in Thibet; the latter substance is, however, imported from China.

The turquoise, real or artificial, is universally worn in rings, necklaces, &c., and large, amber-like beads are a favourite ornament; but it is uncertain whether they are natural products of Thibet. The latter are apparently composed of turpentine mixed with some hardening material. Numerous imitations of turquoise are imported from China; and real but not valuable stones are sent, *viâ* Cashmere (but from what locality is not stated). The only test of a real stone that is resorted to by the Thibetans is to make a fowl swallow it; if real it will pass through unchanged.

In conclusion, we may add that Dr. Campbell's articles in *The Phoenix* contain much valuable matter on the geography, the government, and army of Thibet, the personal habits, customs, and ceremonies of the Thibetans, their religious festivals, the seasons, soil, and agriculture of the country, the wages of labour, and the most prevalent diseases. Amongst "Things not generally known," we may mention *Goomtook*, or *The laughing disease*, which consists of violent fits of laughter with excruciating pain in the throat. It equally attacks men and women, and often proves fatal in a few days.

ON THE CAUSE OF FIXED BAROMETRIC VARIATIONS

THE chief difficulty in the way of explaining the annual and diurnal variations of the barometer by the heating and cooling of the air, appears to be the existence of a double maximum and minimum. To show how such a double maximum and minimum might result from the

* Notices of the Thibetan Gold Mines may be found in several recent numbers of the "Proceedings of the Royal Geographical Society."

changes in the temperature of the dry air alone, is the object of the present paper. I commence with the diurnal variation.

Let us suppose an atmosphere of dry air hardly absorbing any heat from the solar rays, and therefore chiefly heated and cooled by contact with the earth. Let us take the moment when the earth first begins to be heated by the sun's rays. (This will probably take place a little before sunrise, in consequence of the large amount of reflected or diffused heat which accompanies the morning twilight.) The earth then becomes heated at A, while at B, a little more to the west, no heat is yet felt. The earth

at A communicates its heat to the air in contact with it, and the latter expands and becomes lighter than the air in contact with the earth at B. (At C of course the earth is more highly heated than at A, and therefore the air in contact with the earth at C is still lighter.) The immediate consequence is that the heavier air at B rushes into the heated space A D (see fig.), driving out the lighter air which occupies it; and A D becoming filled with heavier air than before, the barometer at A rises. The heating goes on however at A, which remains at a higher temperature than B, until the epoch of greatest heat arrives; and consequently during all this time there is a flow of air from B towards A next the earth, with a flow in the contrary direction at a greater elevation. It might at first sight appear that the barometer at A would go on rising all this time. But a moment's reflection will show us that though it does so at first, it could not continue to do so all through. For as at the epoch of greatest cold (with which we commenced) C, A, and B were sensibly at the same temperature, so they will arrive at sensibly the same temperature at the epoch of greatest heat; and immediately afterwards the direction of the under-current will be reversed, C having become colder than A, while B is hotter. It is therefore evident that during the whole time which has elapsed between the epochs of greatest cold and greatest heat, the two currents will have counter-balanced each other, the under current having carried exactly as much air from B to A as the upper-current has carried from A to B. Making a somewhat rough approximation, we may assume that during the first half of this period the under-current has been in excess, and the barometer at A has risen, while in the latter half the upper-current has been in excess, and the barometer at A has been falling. Immediately after the epoch of greatest heat, the cooler and heavier air at C will displace the air in the space A D, causing the barometer at A to rise. The moment of greatest heat will, therefore, correspond to a minimum reading of the barometer, not a maximum; and after it the barometer will go on rising until half way between it and the moment of greatest cold, when it will again fall until the latter moment. The barometer will, therefore, attain its minimum height at the hours of greatest heat and greatest cold, while the maximum heights will occur at about halfway between these epochs. Now this result appears to conform exactly to observation. It must be recollected that the minimum of temperature occurs not more than half an hour before sunrise, while the maximum is generally not reached for two or three hours after noon. This will explain why the morning barometric maximum seems to be nearly an hour earlier than the evening one. Indeed observation corresponds so exactly with the results arrived at, that I think it will appear that they cannot be seriously modified by the presence of aqueous vapour.

The mean of barometric pressures at different latitudes confirms these results. If the trade-winds extended to the poles—which they probably would do were it not that the parallels of latitude become so narrow before reaching them—on the same principles we might expect a minimum of pressure at the equator and the poles with a maximum at a latitude of about 45°. For the second of these minima we must evidently substitute the limit of the trades, or rather perhaps of the anti-trades, since the latter seem ultimately to become the under-currents; and our maximum will be situated about halfway between this limit and the equator. This agrees with observation. The phenomena of the tides too are analogous. There is low water where the moon's attraction is strongest and where it is feeblest, while high water corresponds to the mean attraction. Putting heat for attraction and the sun for the moon, the diurnal variations of the barometer follow the same law.

This law, however, does not appear to hold so well for the annual barometric changes. We can hardly trace in this case a double maximum in May and November, with minima in January and July. I think, however, that this result may be in part at least explained by the northern and southern shifting of the system of trades and anti-trades. For example, if a place in the northern hemisphere be near this limit (which corresponds to a minimum), the southern movement of the system in winter may cause the barometer to rise instead of falling as we approach the coldest day (supposing of course that it lies to the north of it). On the other hand, at a locality a little to the south of the limit, the northern movement of the system in summer may cause the barometer to rise at the time of greatest heat. I should perhaps notice, however, that the results here arrived at suppose the three points A, B, C to be situated on a horizontal plane, and the specific heat and conductivity of the earth at each of these points to be nearly identical. Hence they cannot be expected to hold for very elevated positions, or for places situated on the sea coast, or the shores of a large lake. They will be found most accurate in the interior of continents, where the land is level, and where the amount of aqueous vapour in the air is comparatively small. This anticipation is also verified by observation, so far as my knowledge reaches.

W. H. S. MONCK

REMARKS ON THE ADAPTIVE COLOURATION OF MOLLUSCA*

NATURALISTS have long recognised the curious cases oftentimes occurring, of the resemblance between the colour of an animal and its immediate surroundings. It had been supposed that climatic influences, or peculiarities of food, or greater or less access to light, had something to do with these coincidences. Mr. Alfred R. Wallace has shown that the varied phases of these phenomena could not be explained by such agents, and in a paper "On Mimicry and other protective resemblances among Animals," published in the *Westminster Review*, July 1867, and since made widely public in his work on "Natural Selection," he shows that the singular resemblances between the colour of animals and their surroundings are mainly brought about by the protection afforded them through greater concealment. Many very interesting examples are then cited from the Vertebrates and Articulates in support of these views. Briefly may be mentioned, as examples, the almost universal sand colour of those animals inhabiting desert tracts; the white colour of those animals living amid perpetual snows; the resemblance seen again and again between the colour of many insects and the places they frequent. Among the hosts of examples cited by Mr. Wallace as illustrating plainly the views he advances, may be mentioned the

* From the Proceedings of the Boston Society of Natural History, vol. xiv., April 5, 1871.

many species of *Cicindela*, or tiger beetle. The common English species, "*C. campestris*," frequents grassy banks, and is of a beautiful green colour, while *C. maritima*, which is found only on sandy sea shores, is of a pale bronzy yellow, so as to be almost invisible.* He then states that a great number of species found by himself in the Malay Archipelago were similarly protected. "The beautiful *Cicindela gloriosa*," of a deep velvety green colour, was only taken upon wet mossy stones in the bed of a mountain stream, where it was with difficulty detected. A large brown species (*C. heros*) was found chiefly on dead leaves in forest paths; and one which was never seen except on the wet mud of salt marshes, was of a glossy olive so exactly the colour of the mud as only to be distinguished when the sun shone, by its shadow. Where the sand beach was coralline and nearly white, I found a very pale *Cicindela*; wherever it was volcanic and black, a dark species of the same genus was sure to be met with."

But little attention has been given to adaptive colouring among the lower invertebrate animals. Darwin, in his last work on the "Descent of Man," calls attention to the statements of Haeckel that the transparency of the Medusæ and other floating animals is protective, since their glass-like appearance renders them invisible to their enemies, though Wallace also alludes to this same feature (p. 258). Mr. Edward Burgess informs me of a species of *Acaleph*, *Polycionia frondosa*, on the coast of Florida which lives in the mud, and is brown in colour. Darwin, while admitting that the transparency of these animals unquestionably aids them to escape the notice of their enemies, yet doubts whether the colour of mollusks affords similar protection. He says, "The colours do not appear in most cases to be of any use as a protection; they are probably the direct result, as in the lower classes, of the nature of the tissues, the patterns and sculpture of the shell depending on its manner of growth" (vol. i. p. 316).

In glancing over our new England Mollusca, however, it seems that we do have very clear evidences of protective adaptations among them, not only in their form, but more particularly in their colour. It would seem strange indeed if this were not so, since so many species of Mollusca form an important portion of the food of many fishes,* and also of certain species of birds.

In a general way, we recall the sombre colours of the shells of most species, varying through different shades of yellow, brown, and green, in this respect resembling the sand, mud, and rocks, or seaweed, in or upon which they live, and we then recall by groups the land snails of our woods, with their almost uniform brown tints, like the dead leaves or rotten wood in which they live.

The freshwater snails have similar shades to match their peculiar habitats.

The freshwater mussels, coloured likewise brown, greenish, or black, accord with their places of refuge.

Among the marine forms we notice the adaptive colouration of certain species very well marked. The common *Littorina* of the coast swarms on the bladder weed, the bulbous portions of which are olive brown in colour, or yellowish, according to age. The shells of the *Littorina* found upon it, present in their varieties these two colours, and are limited to these colours, though now and then delicately banded specimens are seen.

Purpura lapillus, which generally hides beneath overhanging ledges, or is concealed under flat rocks, has gene-

rally a dirty white shell, with, now and then, a specimen bright yellow, or banded with brown. We are not aware of any fish that feeds upon this species, though in the almost universal white colour of the species an adaptive colour may be secured in resembling the white barnacles which oftentimes whiten the rocks by their numbers.

In pools left at low tide where the rocks are often clothed with the red calcareous algae we find the little red Chiton. Certain *Mytili* are green. The young of the large *M. modiolus* has a rough coat of epidermal filaments, looking like the aborescent growth of some Alga or Hydroid.

The few species common to the mud flats exposed by the retreating tide are coloured black or dark olive. *Ilyanassa obsoleta* has the shell black, while the soft parts are quite dark. A related form, *Nassa trivittata*, lives in more sandy places, and has a similarly coloured shell. *Rissoa minuta*, inhabiting mud flats, has a shell dark olive, or nearly black, while other species of *Rissoa* are much lighter in colour. The fronds of the large Laminarian are frequented by *Lacuna vineta* and its variety *fusca*. The first is greenish or purplish horn colour, with darker bands, while the variety *fusca* is uniformly dark brown or chestnut; the colours in both cases quite match the Laminarian upon which they are found. Another species of the same genus, *Lacuna neritoides*, Mr. Fuller has observed spawning on bladder-weed, and its yellowish tinge accords well with its surroundings. *Margarita helicini* I have found in numbers on the large Laminarian, and on seaweed at low-water mark, and its colour is decidedly protective; while other species of *Margarita*, dredged in deep water on shelly ground, are whitish, pearly, or red.

The protective colouring of certain species is well seen upon stones dredged in deep water, the various mollusks adhering to them closely resembling the calcareous algae and the stones themselves.

Species similar to sand beaches are of various sand-coloured shades, as for example *Machera*, *Macra*, *Cochlodesma*, *Cyprina*, the little *Solenomya*, and *Solen*. On muddy ground we notice certain *Tellinas* and other species with white shells. It has been supposed that those species hidden from the light were generally white, and this would seem to be the case when we recall *Mya*, certain species of *Teredo*, *Tellina*, *Pholas*, and other species. Yet we do have cases where the shell is oftentimes conspicuously banded or marked. It might appear that in those species living buried in the mud or sand, the shell was protected by a very thin epidermal layer, and that this layer was eroded, thus exposing the white shell; there are certain species, however, living buried in the mud or sand, which have an epidermal coat, very thick, and dark brown or black; such examples are seen in *Solenomya borealis* and *Glycymeris siliqua*.

It has been noticed that the same species occupying different stations are differently coloured. Dr. A. A. Gould noticed this in regard to *Astarte castanea*; those thrown up from deeper water are darker coloured than those found in quiet sandy places. In his "Report on the Invertebrate Animals of Massachusetts," first edition, p. 78, speaking of the shells found in the sandy harbour of Provincetown, he says: "The colour of all the shells in that harbour is remarkably light."

A very evident case of protective colouring is seen in the three species of *Crepidula* found on our coast. *Crepidula fornicata* is drab, variously rayed and mottled with brown, and it lives attached to stones near the roots of the large Laminarian, or upon stones clothed with algae of similar colours, or attached to the large *Mytilus*. *Crepidula convexa*, a much smaller species, lives on the roots of seaweed. Prof. Perkins records its occurrence on the black shell of *Ilyanassa obsoleta*. This *Crepidula* has a very dark brown shell, according well with the dark colour of its various places of lodgment. *Crepidula plana*

* In an inlet near Salem the writer observed a school of minnows swimming along the bottom, and as they approached a certain point jumped right and left in great alarm. For some time the disturbing cause could not be found. On closer examination, however, a Cottus was seen to open his large mouth and take in several of the little fishes. The Cottus was so perfectly protected by its colours that it was only recognised when the capacious mouth opened, and only then were the minnows alarmed. Just beyond in their track was a rusty tin fruit can, the little tin remaining on it reflecting the rays of the sun, and from this harmless object they all turned frightfully away. In this connection it would be interesting to inquire into the food of fishes in respect to their colours. Those fishes feeding upon Mollusca would certainly not require that protection for concealment as those living upon more active prey.

or *unguiformis* lives within the apertures of larger species of Gasteropods, as *Buccinum*, *Natica*, *Busycos*, and others. The shell of this *Crepidula* is absolutely white.

There are many species that undoubtedly receive protection in allowing foreign substances to grow upon their shells, and these species, oftentimes covered by a dense growth of calcareous or other algæ, are difficult of detection by the experienced collector.

There are also certain species that habitually accumulate foreign substances upon their shells. The little *Pistidium ferrugineum* possibly finds greater immunity from danger in its habit of accumulating a ferruginous deposit on that portion of the shell most conspicuous. *Nucula delphinodonta* has likewise a similar habit. The delicate *Lyonsia arenosa*, with its habit of entangling particles of sand in its epidermal filaments, undoubtedly finds protection in this peculiarity.

It was not the intention to go outside of New England species in citing these examples, but in this connection I cannot forbear mentioning the tropical genus *Phorus*. The species are said to frequent rough bottoms, and to scramble over the ground, like the Strombs, and not to glide evenly. This peculiar manner of moving would render them very conspicuous, and it is curious to observe that most of the species attach foreign substances to the margins of their shells as they grow, so that when a shell has attained its growth, it is almost completely concealed by fragments of shells large and small, spines of Echini, bits of coral, and stones.

These few observations are offered (and they might be multiplied) with the belief that if there is any truth in the theory of protective colouring, as advanced by Wallace, the various colours of Mollusca in many cases can be explained, and the occurrence of varieties in colour are also accounted for by the same theory.

EDWARD S. MORSE

SCIENCE AT THE LONDON SCHOOL BOARD

PROF. J. J. SYLVESTER has issued his address as candidate for election to the London School Board for Marylebone in the room of Prof. Huxley. The importance of having at least one representative of Science on the Board induces us to print his Address in full. It must be obvious that many subjects will come before the Board wherein the opinion of a man of Prof. Sylvester's scientific training will be of the highest value; and we heartily wish the Board may be fortunate enough to obtain the additional strength which will be secured by his election.

"LADIES AND GENTLEMEN,—An influential body of ratepayers have appealed to me as a man of science, to offer my services on the London School Board.

"It has been represented to me, as the wish of your great constituency, that Prof. Huxley should be replaced by one who, like himself, has made the scientific part of education the chief business of his life. On this ground I have ventured to place myself in your hands.

"My University career at Cambridge, added to my experience both as Professor of Natural Philosophy at University College, London, and subsequently as Government Professor of Mathematics during a period of fifteen years at the Royal Military Academy at Woolwich (from which I have recently retired), have given me considerable knowledge of educational matters in England. My position as Corresponding Member of the Institute of France, as Corresponding Member of the Royal Academy of Science of Berlin, as Foreign Member of the Royal Academy of Science of Naples, and other learned corporations, gives me an early and accurate knowledge of what is passing in the chief intellectual centres of the Continent. I have ample leisure for the work that is to be done, not only in

attending the ordinary meetings of the Board, but also the various sub-committees on which the general working of the Act devolves, as well as the divisional and district committees, on the efficiency of which the local benefit of that Act depends.

"If you send me to the London School Board, I shall be prepared, while looking forward to the gradual adoption of a National system of Education, to adhere to that wise and moderate compromise by which, without violation of principle, you may obtain the use of existing school machinery.

"I have the honour to be, Ladies and Gentlemen, your obedient servant,

"J. J. SYLVESTER, LL.D., F.R.S.

"Central Committee Room,
25, Great Quebec Street, Marylebone Road, W."

Dr. Sylvester has already received the promise of the support of the following scientific men:—Sir Chas. Wheatstone, D.C.L.; Prof. Sharpey (Sec. Royal Society); Prof. Busk, Pres. Royal Col. Surgeons; Phillip H. Calderon, R.A.; William Heywood, C.E.; E. H. Lawrence, F.S.A.; J. Norman Lockyer, F.R.S.; J. Gerstenberg, F.R.G.S.; J. Gwyn Jeffreys, F.R.S.; Nicholas Trübner, M.R.A.S.; Prof. T. Hewitt Key, F.R.S.; Dr. Wilson; David Forbes, F.R.S.; H. W. Bates, Sec. Royal Geog. Society; Henry Holiday; Henry Watts, F.R.S.; Dr. Pick; Thomas Woolner, A.R.A.; Professor Williamson, F.R.S.; Charles Brooke, F.R.S.; Sir Henry Thompson; Colonel Stuart Wortley; Dr. Forbes Winslow, F.R.S.; Joseph Durham, A.R.A.; C. Murchison, M.D., F.R.S.; Prof. Henry Charlton Bastian, F.R.S.; William Perkins; Noel Humphreys, F.S.A.; T. Spencer Cobbold, M.D., F.R.S.; A. W. Bennett, F.L.S.; Sir Julius Benedict; Prof. W. Warrington Smyth, F.R.S.; George Cruickshank; Prof. J. Percy, F.R.S.; George Harley, M.D., F.R.S.; Nevil S. Maskelyne, F.R.S.; W. S. Dallas, Sec. Geol. Soc.; Prof. G. C. Foster, F.R.S.; William Chaffers, F.S.A.; J. J. Stevenson, F.R.G.S.; and J. H. Pepper.

NOTES

WE congratulate the Science and Art Department on a resolution at which they have just arrived, in consequence of applications from science schools, to form collections of such specimens, models, diagrams, &c., as are best adapted for teaching the various branches of science which the Department aids by grants. It is proposed that collections shall be sent on loan for short periods to the local schools, to assist them in furnishing themselves with the necessary apparatus. The specimens and apparatus already in the Educational Department of the South Kensington Museum have been arranged for examination under the different subjects of instruction, and a letter has been forwarded to all the Examiners of the Department, requesting them to inspect the collections, with the view of advising what portion of them they consider may with advantage form part of the proposed travelling collections; what additions should be made, so as to give the science schools an idea of what they would require for a complete outfit; and what are the best and cheapest forms of apparatus, &c., for them to provide themselves with.

A FEW months ago we noticed the expedition to Moab which, by the aid of the British Association, was organised by Dr. Ginsburg and Dr. Tristram. We have now to announce the safe return of Dr. Ginsburg, and hope soon to be able to state some of the results of the expedition, which we have reason to believe are both numerous and interesting.

THE Society for the Encouragement of Arts, Manufactures, and Commerce is about to organise examinations in the science and technology of the various arts and manufactures of this country, which shall be conducted by a Board of Examiners, capable of testing the practical knowledge and skill required in the application of the scientific principles involved in each art or

manufacture. We heartily commend this movement on the part of the Society of Arts, and may probably recur to the subject at some future time.

THE Geologists' Association has made the following excursion arrangements for March and April:—Thursday, March 21, a visit to the Museum of Practical Geology, under the guidance of Prof. Morris. Tuesday, April 2, an excursion to Maidstone, under the direction of Mr. W. H. Bensted and Prof. Tennant. Upon arriving at Maidstone the party will visit the Charles Museum, and afterwards the fine sections of the Lower Greensand, exposed in the "Iguanodon Quarries." The Kentish Rag is here well seen *in situ*. Subsequently the party will proceed to Aylesford, crossing the Medway at Allington Lock, and the Gault, Lower Greensand, and Valley Deposits yielding Mammalian Remains, there exposed, will be inspected. Saturday, April 13, an excursion to Watford and Bushey, under the leadership of Mr. John Hopkinson. The special object of interest will be the sections of the Chalk, the Woolwich and Reading Series, and of the London Clay (Basement Bed). Saturday, April 27, excursion to Hampstead, directed by Mr. Caleb Evans and Mr. S. R. Pattison. The party will visit the shaft of the Midland Railway Tunnel, and afterwards proceed to Hampstead Heath to observe the sections of the Bagshot Sands here exposed, as well as the Physiography of the District. The Annual Report of the Association for 1871 furnishes satisfactory evidence of the prosperity and progress of this useful institution. We have from time to time given so full a report of its proceedings that we need not do more than congratulate the Society on its success.

THE Board of Directors of the Edinburgh School of Art have appointed Dr. Robert Brown to the newly-created Lectureship on Geology and Palæontology, viewed more especially in the relation of the science to landscape painting, sculpture, architecture, and other fine arts and industries.

A LECTURE will be delivered for the Society of Telegraph Engineers at the Institution of Civil Engineers, 25, Great George Street, Westminster, on Wednesday, March 27, at 7.30 P.M., by Captain P. H. Colomb, R.N., on "Telegraphing at Sea."

A LECTURE will be delivered at the London Institution, Finsbury Circus, this evening (March 21) at 7.30 P.M., on "How Plants are Fertilised," by Mr. A. W. Bennett.

MESSRS. SAMPSON LOW AND CO. have in the press Captain Butler's account of his connection with the Red River Expedition in 1869-70, and of his subsequent travels and adventures in the Manitoba country and across the Saskatchewan Valley as civil agent for the Government.

ONE of the best papers on local geology which we have recently come across was read by Mr. Thos. Beesley at the Annual Meeting of the Warwickshire Naturalists' and Archaeologists' Field Club on March 5, "On the Geology of the neighbourhood of Banbury." Mr. Beesley gave a detailed account of the various strata represented in the neighbourhood, and the fossils found in them, and he ably sustained the view, in opposition to that held by Prof. Phillips, that the Inferior Oolite extends far into Oxfordshire.

THE *Traveller*, which has now been in existence nearly a year, continues to contain excellent articles on travel and geographical research, of special interest to English and Americans.

We have received the seventh Annual Report of the Massachusetts Institute of Technology. It was established on the principle that all the studies and exercises of the first and second years should be pursued by the whole school. At the beginning of the third year, each student selects one of the following special

courses of study:—1. A course in Mechanical Engineering; 2. Civil and Topographical Engineering; 3. Geology and Mining Engineering; 4. Building and Architecture; 5. Chemistry; 6. Science and Literature; 7. Natural History. These courses differ widely, but certain general studies are common to them all. It is intended to secure to every student, whatever his special course of study, a liberal mental development and general culture, as well as the more strictly technical education which may be his chief object. The course in Science and Literature, and the course in Natural History, differ from the others in having a less distinctly professional character. The former offers a sound education, based on the sciences and modern literature, and furnishes, with its wide range of elective studies, a suitable preparation for any of the departments of active life, or for teaching science. The course in Natural History affords an appropriate general training for those whose ulterior object is the special pursuit of Geology, Mineralogy, Botany, Zoology, or of Medicine, Pharmacy, or Rural Economy.

SINCE the days of its foundation, the Federal School at Zurich has, according to the *Mining Magazine and Review*, not only fulfilled its object, but has even surpassed the most well-founded hopes. In fact, each year the number of students has increased; the most distinguished professors have been happy to accept the offer of a chair in a college so flourishing; and it has already produced a number of distinguished pupils, whose reputation has placed it among the first establishments of the kind in Europe. The Swiss pupils are surpassed in number by students drawn from all the other nations of Europe, but chiefly from Russia, Poland, and Hungary, while there is a fair proportion both of Americans and Asiatics. All the cantons, however, are well represented, and the French and Italian cantons, in spite of the difference of tongue, send a very good contingent of their children. So many candidates presented themselves for admission in 1871, that it was not possible to accommodate them all; and this has again brought to the surface the idea of a Federal University, which will no doubt be speedily realised.

THE *British Medical Journal* says that the people of Rome are very much interested just now in the fate of a poor fellow, Cipriani, who has swallowed a fork in public, prongs downwards, and who is now suffering, in consequence, agonies which are the subject of daily bulletin. Some comfort may be derived by his friends from the record lately published of Mr. Lund's patient at Manchester, who survived swallowing a dessert knife six inches long; and from the perusal of a recent article in the *Journal de Médecine et de Chirurgie*, in which instances are cited where the alimentary canal has safely supported the most unexpected foreign bodies—among others, lizards, a file, a tea-spoon, a bat; and, finally, from the whimsical but melancholy instance of a man who, to amuse himself, swallowed successfully and safely a five-franc piece, a closed pocket-knife, and a coffee-spoon, but killed himself at last in the vain effort to digest a pipe.

THE *Medical Times and Gazette* of March 16 contains some interesting remarks on Prof. Laycock's Lecture on Ears delivered in Paris in 1862, a subject of special interest in connection with the recent Tichborne trial. The woodcuts with which the article is illustrated show the remarkable similarity between the square lobes ear, met with in cases of dementia, and the ear of the chimpanzee.

DURING the last few days of December 1871, Adelaide, in South Australia, was visited, according to the *Gardener's Chronicle*, by dense clouds of locusts. Dr. Schomburgk describes the visitation as a very remarkable one. He says the air was quite darkened with them. They came from the north, and devoured everything looking green. Nothing remained of the fine lawns in the Botanic Garden but the bare brown earth.

A RICH instance of the mode in which the phenomena of nature present themselves to certain minds is furnished by the following extract from the *Prophetic News* for March 1872, published by G. J. Stevenson, 54, Paternoster Row:—"St. John in the Apocalypse has described his vision of the descent of 'the city of the New Jerusalem' into the air. . . . The Royal city may at first appear as a comet, which astronomers may be unable to understand, for its luminosity and stationary position in the eastern hemisphere may at first be but just discoverable. The news may then flash all over the globe by means of the telegraph. The unusual brilliancy of the aurora borealis seems a fitting harbinger, together with the spots which appear in the sun, of the approaching climax (Luke xxi. 25, 26), for through the prophetic telescope alone can we realise the intention of these wonderful phenomena. I shall be glad if some of your correspondents who may have given their thought to these points would avail themselves of the *Prophetic News* to help others to a better understanding of so important a subject."

In the last year there was exported from Nicaragua 100 dols. worth of the waters of Nejapa, reported to have the virtue of curing drunkenness. This may be recommended to the Liquor League as better than a Maine Liquor Law. In the neighbouring State of Columbia, it is asserted by natives and Europeans, that there is an Indian cure for drunkenness.

ON the 16th of January two slight shocks of earthquake were felt at Valparaiso at 10.20 P.M. The weather was intensely cold.

ON the night of the 10th of January several shocks of earthquake were felt in Arequipa, in Peru, but no damage was done. It was observed they occurred a few hours after the new moon, and coincided with one of the highest tides of the year.

ON the 31st of January a severe shock of earthquake was felt at Paini, in Bengal.

In the month of January there were frequent shocks of earthquake at Broossa, in Asia Minor.

ON Jan. 14 and 15 three shocks of earthquake were felt in the English hill-town of Darjeeling, in the Himalayas.

A SLIGHT shock of earthquake was felt in the middle of October at Memeodsbad, in the Ahmedabad Collectorate, Bombay Presidency.

ON the 23rd Jan. there was an earthquake at Guayaquil, in Ecuador.

In January the heaviest fall of snow known for years took place in the hills of the Deyrsh Dhoon.

LARGE deposits of coal have been discovered at Cobquecura, in the province of Itata, Chile.

FURTHER important mineral discoveries are officially reported from Bolivia, which are expected to produce great results. In the Chaco on the road from La Paz to Fungas silver ore has been found yielding 12,000 ounces per ton, or half silver. A hundred claims were at once taken up. On the Llisa and Condormanana hills, near San Andres de Mochaca, veins of gold have been found, as well as in Vilaquil, eighteen miles from La Paz, where ancient winnowing grounds have been recognised.

ACCORDING to a report made by the Rev. Father Wolf to the Government of Ecuador, there are extensive fossil remains of the Tertiary and Quaternary epoch on the coast of Manabi and near Punin. Besides the mastodon the fossil horse is found, showing that in pre-historic times such animals were found there, though they became extinct, and the present race was introduced by the Spaniards.

IN Bolivia has been discovered an ancient mine, known as the Narango, twelve miles S. of Antofogasta, in the Mejillones district, near the Pacific. The vein is reported as composed of ochre-coloured ore, backed by a stratum, 2½ in. thick, of copper studded with gold, and containing about 20 per cent. of this precious metal.

A CORRESPONDENT of the *Ceylon Times* draws attention to the circumstance that that island is, as he believes, on the eve of an important change of climate, depending on the great cycle of thirty or thirty-three years. The past thirty years have, he maintains, shown a complete contrast to the previous thirty years, with manifestly different effects on animal and vegetable life, from the much smaller amount of rain. The next cycle of thirty years will be, he thinks, above the average, wet.

A SUIT has lately taken place in the High Court of Madras respecting a two-mouthed cow, the value of which is estimated at 1,000*l.*, as large sums were made by exhibiting it. She had been seized by the sheriff, as is alleged, on wrongful distraint.

THE Ipecacuanha plants in the Neilgherries are flourishing. Two have blossomed, but have yielded no seed. Twelve plants in good condition were received at the Calcutta Botanic Gardens from England in August.

THE English Vice-Consul at Ciudad Bolivar, on the Orinoco River, Venezuela, reports that an old woman had applied an efficacious remedy for yellow fever and black vomit. It is the juice of the leaves of the vervain plant, which is obtained by bruising, and is taken in small doses three times a day. Injections of the same juice are also administered every two hours until the bowels are completely relieved of their contents. The medical men have adopted the remedy, and the number of fatal cases have been much reduced. The leaves of the female plant alone are used.

THE wild elephant which has lately destroyed 151y-six lives in the Central Provinces of India and committed such ravages, was shot on November 15 by two officers of the Government. The night before his death he killed ten persons.

A GOOD deal of attention has been excited among Egyptologists by the comparatively recent discovery in excavations made at Tanis, on the eastern or Pelusiac branch of the Nile, of a trilingual stone, somewhat of the character of the celebrated Rosetta stone, but much more perfect, and believed to be of about two hundred and fifty years' greater antiquity. This, which is now deposited in the Museum of Egyptian Antiquities at Cairo, is a perfect stela, about six feet high, two and a half feet broad, and one foot thick, the summit being arched.

PUCHIMURREE or Pachmari, in the central provinces of India, is now to be marked on our maps as a town; this hill site having been successfully established as a sanitarium for English soldiers in 1870.

A SHOWER of stones is reported from Rosario, in December. A great tempest was felt, ending in a shower of stones from N.W. to S.W., and doing much damage. The shower lasted ten minutes, and the stones were abundant and large, weighing from a nut in size to a pigeon's egg. The corn fields have severely suffered. It is remarked the like occurrence had not been seen for many years, so it is to be inferred such a phenomenon is not unknown. As the Bernstadt colony was affected some European observations may be received.

TWO new discoveries of gold are announced, the one in the Transvaal district near Natal, where the gold is stated to exist in large quantities, and the other in Manitoba, in Canada.

THE STUDY OF NATURAL HISTORY

A LECTURE under this title delivered at the Royal Artillery Institution, Woolwich, by the Rev. Canon Kingsley, has just been published, containing some admirable remarks on the relation between the soldier and the naturalist, from which we cannot forbear making the following extracts.

After some introductory matter, he proceeded:—

"It seemed to me, therefore, that I might, without impertinence, ask you to consider a branch of knowledge which is becoming yearly more and more important in the eyes of well-educated civilians—of which, therefore, the soldier ought at least to know something, in order to put him on a par with the general intelligence of the nation. . . .

"Let me, however, reassure those who may suppose, from the title of my lecture, that I am only going to recommend them to collect weeds and butterflies, 'rats and mice, and such small deer.' Far from it. The honourable title of Natural History has, and unwisely, been restricted too much of late years to the mere study of plants and animals; but I desire to restore the words to their original and proper meaning—the History of Nature; that is, of all that is born, and grows—in short, of all natural objects.

"If any one shall say, by that definition you make not only geology and chemistry branches of natural history, but meteorology and astronomy likewise—I cannot deny it; they deal, each of them, with realms of Nature. Geology is, literally, the natural history of soils and lands; chemistry the natural history of compounds, organic and inorganic; meteorology the natural history of climates; astronomy the natural history of planetary and solar bodies. And more, you cannot now study deeply any branch of what is popularly called Natural History—that is, plants and animals—without finding it necessary to learn something, and more and more as you go deeper, of those very sciences. As the marvellous interdependence of all natural objects and forces unfolds itself more and more, so the once separate sciences, which treated of different classes of natural objects, are forced to interpenetrate, as it were, and supplement themselves by knowledge borrowed from each other. Thus—to give a single instance—no man can now be a first-rate botanist unless he be also no mean meteorologist, no mean geologist, and—as Mr. Darwin has shown in his extraordinary discoveries about the fertilisation of plants by insects—no mean entomologist likewise.

"It is difficult, therefore, and indeed somewhat unwise and untair, to put any limit to the term Natural History, save that it shall deal only with nature and with matter, and shall not pretend—as some would have it do just now—to go out of its own sphere to meddle with moral and spiritual matters. But, for practical purposes, we may define the natural history of any given spot as the history of the causes which have made it what it is, and filled it with the natural objects which it holds. And if any one would know how to study the natural history of a place, and how to write it, let him read—and if he has read its delightful pages in youth, read once again—that hitherto unrivalled little monograph, White's 'History of Selborne;' and let him then try, by the light of improved science, to do for any district where he may be stationed what White did for Selborne nearly 100 years ago. Let him study its plants, its animals, its soils and rocks, and last, but not least, its scenery, as the total outcome of what the soils, and plants, and animals have made it. I say, have made it. How far the nature of the soils and the rocks will affect the scenery of a district may be well learnt from a very clever and interesting little book of Prof. Geikie's on 'The Scenery of Scotland, as affected by its Geological Structure.' How far the plants and trees affect not merely the general beauty, the richness or barrenness of a country, but also its very shape; the rate at which the hills are destroyed and washed into the lowland; the rate at which the seaboard is being removed by the action of waves—all these are branches of study which is becoming more and more important.

"And even in the study of animals and their effects on the vegetation, questions of really deep interest will arise. You will find that certain plants and trees cannot thrive in a district, while others can, because the former are browsed down by cattle, or their seeds eaten by birds, and the latter are not; that certain seeds are carried in the coats of animals, or wafted abroad by winds—others are not; certain trees destroyed wholesale by insects, while others are not; that in a hundred ways the animal and vegetable life of a district act and react upon each

other, and that the climate, the average temperature, the maximum and minimum temperatures, the rainfall, act on them, and in the case of the vegetation, are reacted on again by them. The diminution of rainfall by the destruction of forests, its increase by re-planting them, and the effect of both on the healthiness or unhealthiness of a place—as in the case of the Mauritius, where a once healthy island has become pestilential, seemingly from the clearing away of the vegetation on the banks of streams—all this, though to study it deeply requires a fair knowledge of meteorology, and even a science or two more, is surely well worth the attention of any educated man who is put in charge of the health and lives of human beings.

"You will surely agree with me that the habit of mind required for such a study as this, is the very same as is required for successful military study. In fact, I should say that the same intellect which would develop into a great military man, would develop also into a great naturalist. I say, intellect. The military man would require—what the naturalist would not—over and above his intellect, a special force of will, in order to translate his theories into fact, and make his campaigns in the field and not merely on paper. But I am speaking only of the habit of mind required for study; of that inductive habit of mind which works, steadily and by rule, from the known to the unknown—that habit of mind of which it has been said:—'The habit of seeing; the habit of knowing what we see; the habit of discerning differences and likenesses; the habit of classifying accordingly; the habit of searching for hypotheses which shall connect and explain those classified facts; the habit of verifying these hypotheses by applying them to fresh facts; the habit of throwing them away bravely if they will not fit; the habit of general patience, diligence, accuracy, reverence for facts for their own sake, and love of truth for its own sake; in one word, the habit of reverent and implicit obedience to the laws of Nature, whatever they may be—these are not merely intellectual, but also moral habits, which will stand men in practical good stead in every affair of life, and in every question, even the most awful, which may come before us as rational and social beings.' And specially valuable are they, surely, to the military man, the very essence of whose study, to be successful, lies first in continuous and accurate observation, and then in calm and judicious arrangement.

"Therefore it is that I hold, and hold strongly, that the study of physical science, far from interfering with an officer's studies, much less unfitting for them, must assist him in them, by keeping his mind always in the very attitude and the very temper which they require. . . .

"I should like to see the study of physical science an integral part of the curriculum of every military school. I would train the mind of the lad who was to become hereafter an officer in the army—and in the navy likewise—by accustoming him to careful observation of, and sound thought about, the face of nature—of the commonest objects under his feet, just as much as of the stars above his head; provided always that he learnt, not at second-hand from books, but where alone he can really learn either war or nature—in the field, by actual observation, actual experiment. A laboratory for chemical experiment is a good thing, it is true, as far as it goes; but I should prefer to the laboratory a naturalists' field club, such as are prospering now at several of the best public schools, certain that the boys would get more of sound inductive habits of mind, as well as more health, manliness, and cheerfulness, amid scenes to remember which will be a joy for ever, than they ever can by bending over retorts and crucibles, amid smells even to remember which is a pain for ever.

"But I would, whether a field club existed or not, require of every young man entering the army or navy—indeed, of every young man entering any liberal profession whatsoever—a fair knowledge, such as would enable him to pass an examination, in what the Germans call *Erd-kunde* (earth-lore)—in that knowledge of the face of the earth and of its products for which we English have as yet cared so little that we have actually no English name for it, save the clumsy and questionable one of physical geography, and I am sorry to say, hardly any readable school books about it, save Keith Johnston's 'Physical Atlas'—an acquaintance with which last I should certainly require of young men.

"It does seem most strange—or rather will seem most strange 100 years hence—that we, the nation of colonies, the nation of sailors, the nation of foreign commerce, the nation of foreign military stations, the nation of travellers for travelling's sake, the

nation of which one man here and another there (as Schleiden sets forth in his book, 'The Plant,' in a charming ideal conversation at the Travellers' Club) has seen and enjoyed more of the wonders and beauties of this planet than the men of any nation, not even excepting the Germans—that this nation, I say, should as yet have done nothing, or all but nothing, to teach in her schools a knowledge of that planet, of which she needs to know more, and can if she will know more, than any other nation upon it. . . .

"Thus much I can say just now—and there is much more to be said—on the practical uses of natural history. But let me remind you, on the other side, if natural history will help you, you in return can help her; and would, I doubt not, help her, and help scientific men at home, if once you look fairly and steadily at the immense importance of natural history—of the knowledge of the 'face of the earth.' I believe that all will one day feel, more or less, that to know the earth *on* which we live, and the laws of it *by* which we live, is a sacred duty to ourselves, to our children after us, and to all whom we may have to command and to influence; ay, and a duty to God likewise. For is it not an act of common reverence and faith towards Him, if He has put us into a beautiful and wonderful place, and given us faculties by which we can see, and enjoy, and use that place—is it not a duty of reverence and faith towards Him to use those faculties, and to learn the lessons which He has laid open for us? If you feel that, as I say you all will some day feel, you will surely feel likewise that it will be a good deed—I do not say a necessary duty, but still a good deed and praiseworthy—to help physical science forward, and add your contributions, however small, to our general knowledge of the earth. And how much may be done for science by British officers, especially on foreign stations, I need not point out. I know that much has been done, chivalrously and well, by officers, and that men of science own them, and give them hearty thanks for their labours; but I should like, I confess, to see more done still. I should like to see every foreign station, what one or two highly-educated officers might easily make it—an advanced post of physical science, in regular communication with our scientific societies at home, sending to them accurate and methodic details of the natural history of each district—details $\frac{82}{100}$ of which might seem worthless in the eyes of the public, but which would all be precious in the eyes of scientific men, who know that no fact is really unimportant, and more, that while plodding patiently through seemingly unimportant facts, you may stumble on one of infinite importance, both scientific and practical.

"There are those, lastly, who have neither time nor taste for the technicalities, the nice distinctions, of formal natural history; who enjoy Nature, but as artists or as sportsmen, and not as men of science. Let them follow their bent freely: but let them not suppose that in following it they can do nothing towards enlarging our knowledge of Nature, especially when on foreign stations. So far from it, drawings ought always to be valuable, whether of plants, animals, or scenery, provided only they are accurate; and the more spirited and full of genius they are, the more accurate they are certain to be; for Nature being alive, a lifeless copy of her is necessarily an untrue copy. Most thankful to any officer for a mere sight of sketches will be the closet botanist, who, to his own sorrow, knows three-fourths of his plants only from dried specimens; or the closet zoologist, who knows his animals from skins and bones. And if any one answers, 'But I cannot draw,' I rejoice, you can at least photograph. If a young officer, going out to foreign parts, and knowing nothing at all about physical science, did me the honour to ask me what he could do for science, I should tell him, learn to photograph; take photographs of every strange bit of rock formation which strikes your fancy, and of every widely-extended view which may give a notion of the general lie of the country. Append, if you can, a note or two, saying whether a plain is rich or barren; whether the rock is sandstone, limestone, granitic, metamorphic, or volcanic lava; and if there be more rocks than one, which of them lies on the other; and send them to be exhibited at a meeting of the Geological Society. I doubt not that the learned gentlemen there will find in your photographs a valuable hint or two, for which they will be much obliged. I learnt, for instance, what seemed to me most valuable geological lessons, from mere glances at drawings—I believe from photographs—of the Abyssinian ranges about Magdala.

"Or again, let a man, if he knows nothing of botany, not trouble himself with collecting and drying specimens; let him simply photograph every strange tree or new plant he sees, to give a general notion of its species, its look; let him append,

where he can, a photograph of its leafage, flower, fruit, and send them to Dr. Hooker, or any distinguished botanist, and he will find that, though he may know nothing of botany, he will have pretty certainly increased the knowledge of those who do know.

"The sportsman, again—I mean the sportsman of that type which seems peculiar to these islands, who loves toil and danger for their own sakes; he surely is a naturalist, *ipso facto*, though he knows it not. He has those very habits of keen observation on which all sound knowledge of nature is based; and he, if he will—as he may do without interfering with his sport—can study the habits of the animals, among whom he spends wholesome and exciting days.

"The two classes which will have an increasing, it may be a preponderating, influence on the fate of the human race for some time, will be the pupils of Aristotle and those of Alexander—the men of science and the soldiers. They, and they alone, will be left to rule; because they alone, each in his own sphere, have learnt to obey. It is therefore most needful for the welfare of society that they should pull with, and not against, each other; that they should understand each other, respect each other, take counsel with each other, supplement each other's defects, bring out each other's higher tendencies, counteract each other's lower ones. The scientific man has something to learn of you, gentlemen, which I doubt not that he will learn in good time. You, again, have (as I have been hinting to you to-night) something to learn of him, which you, I doubt not, will learn in good time likewise. Repeat, each of you according to his powers, the old friendship between Aristotle and Alexander; and so, from the sympathy and co-operation of you two, a class of thinkers and actors may yet arise which can save this nation, and the other civilised nations of the world, from that of which I had rather not speak, and wish that I did not think, too often and too earnestly.

"I may be a dreamer; and I may consider in my turn, as wilder dreamers than myself, certain persons who fancy that their only business in life is to make money, the scientific man's only business to show them how to make money, and the soldier's only business to guard their money for them. Be that as it may, the finest type of civilised man which we are likely to see for some generations to come, will be produced by a combination of the truly military with the truly scientific man. I say, I may be a dreamer; but you at least, as well as my scientific friends, will bear with me; for my dream is to your honour."

SCIENTIFIC INTELLIGENCE FROM AMERICA*

A LATE number of the *College Courant*, of New Haven, contains a detailed account of the exploring expedition under Prof. Marsh, which occupied the greater part of the warm season of 1871, and of which we have already furnished occasional notices to our readers. The general plan, as already stated, embraced excursions from several points, exploring as many different fields, with special reference to the examination of regions comparatively little known. The first starting-point of operations was Fort Wallace, and from this post the cretaceous deposits of South-Western Kansas and the region of the Smoky River were investigated. The second proceeded from Fort Bridger in Western Wyoming, to examine the ancient tertiary lake basin previously discovered by Prof. Marsh. Salt Lake City was the initial point of the third exploration, and the party proceeded thence to the Shoshone Falls, on Snake River, and from there to Boise City, in Idaho; thence they passed over the Blue Mountains to the head waters of the John Day River, and followed down to Cañon City. On the route they made extensive collections of fossil fishes. They also explored two basins, one of the Pliocene and the other of the Miocene age, and in these remains of extinct animals were found in large numbers; the upper bed containing the bones of the elephant, rhinoceros, lion, &c., with several species of the fossil horse; the lower and older basin was found to contain species of the rhinoceros, oreodon, turtles, &c. From this point the party proceeded to the Columbia, and thence to Portland, Oregon, where they took a steamer to San Francisco. Here the expedition divided, a portion going to the Yosemite and elsewhere, while several, with Prof. Marsh, sailed, *via* Panama, for New York, reaching that

* Communicated by the Scientific Editor of *Harper's Weekly*.

city on the 14th of January. We understand that the expedition was thoroughly successful in every respect, securing the collection of large numbers of fossils, as also numerous skeletons of recent animals, together with valuable antiquities, &c. The expense of the exploration amounted to nearly 15,000 dolrs., exclusive of the value of the services rendered by the Government. This was defrayed entirely by the gentlemen composing the party; and it is understood that the material results are to be placed in the Museum of Yale College, which will thereby be rendered the richest in America in this department of natural history.—According to Dr. Petermann, the peak of Itatiaiou, the highest mountain in Brazil, was ascended during the past summer and its altitude determined by Mr. Glaziou, the Director of the Imperial Parks in Rio de Janeiro. It proved to have an elevation of 8,899 English feet, being somewhat less than had been previously estimated. Many species of plants were found on the mountain, and what is of great interest, a large number of Alpine species, especially of *Compositæ*, were collected at from three to seven hundred metres below the summit.—The report of progress for 1870 of the Geological Survey of Ohio, under the direction of Prof. J. S. Newberry, has just been published at Columbus, forming a volume of nearly 600 pages, with a number of accompanying maps and sections. The volume contains, besides a report of progress of 1870, a sketch of the structure of the lower coal measures in North-Western Ohio, by Prof. Newberry; the report of labours in the second geological district, by Prof. E. B. Andrews, and on the geology of Highland County, by Prof. Orton; the report of the Agricultural Survey of the State, by Mr. J. H. Klippart; a report of the chemical department, by Prof. Wormley; sketches of the geology of several counties, by Messrs. M. C. Read and E. Gilbert; a sketch of the present state of the iron manufacture in Great Britain, by W. W. Porter; and a sketch of the present state of the steel industry, by Henry Newton. All these subjects are treated with great care, and the whole volume bears ample testimony to the ability of the chief geologist and the industry of his assistants. This volume is intended as simply preliminary to the final report, which Prof. Newberry hopes to have embodied in four volumes—two of them devoted to geology and palæontology, one to economical geology, and one to agriculture, botany, and zoology. The materials for these volumes are in advanced stage of forwardness, and will embrace monographic treatises on the several subjects, which will be of the utmost benefit in ascertaining and developing the resources of the State.—A society was organised in New York some time since under the name of the "Palestine Exploration Society," with the Rev. Dr. J. P. Thompson, chairman, Dr. Howard Crosby, secretary, and James Stokes, junr., treasurer, with a list of members including the principal archaeologists of the Eastern States. Its first report was published some time ago, embracing an account of the American explorers in Palestine, and the proceedings of the English Palestine Exploration Society, notices of the late explorations in Jerusalem, the Moabite stone, &c., and concluding with an appeal to all persons interested for contributions of funds to aid in carrying out the proposed researches of the society. The field of investigation proposed includes the territory east of the Dead Sea and the Jordan Valley, as also Hermon, Lebanon, and the valleys and plains of Northern Syria. A simultaneous prosecution of researches in this field by two such bodies as the American and English societies will probably be productive of very important results, especially if supported with proper official documents from the Turkish Governments. As so much of what is now on record in regard to the geography and condition of Palestine is due to Americans, it is much to be hoped that the work may be continued by them toward a successful completion.

SCIENTIFIC SERIALS

Annalen der Chemie und Pharmacie viii. Supplement band, 3 Heft. Hesse has contributed a lengthy paper on the alkaloids of opium. It is the most exhaustive essay on the rarer alkaloids that has yet been published. He has examined minutely the following:—Pseudomorphin, laudamine, codamine, narcotine, papaverine, nitropapaverine, cryptine, nitrocryptine, protopine, laudanose, and hydrocaratarine, and numerous salts of each of the above. The author groups the alkaloids into four classes, the morphine, thebaine, papaverine, and narcotine groups, and gives the distinctive characters with which the members of these groups dissolve in pure concentrated sulphuric acid. Marignac

follows with a long communication "On the specific heat, density, and expansion of certain solutions." Bousingault has made some experiments on the freezing of water. He took an exceedingly strong steel cylinder, placed in it a small steel bullet, and filled it entirely with water at 4° C, the cylinder was then closed by means of a cap, so that it was absolutely tight; the cylinder was exposed to a temperature of -24° for some time, but the water inside was not frozen, as was proved by the mobility of the bullet in the interior. Immediately on opening the cylinder and relieving the pressure, the water became a mass of ice.

THE *Geological Magazine* for February (No. 92) opens with some excellent notes on fossil plants by Mr. Carruthers, illustrated with a plate and several woodcuts. The subjects here referred to are the *Paleopteris hibernica*, the presence of sporangia belonging to the *Hymenophyllæ* in coal, *Osmandites Dawberi*, the genus *Antholites*, a revision of the British forms belonging to which is given, the coniferous wood of Craiglachie quarry and *Peltocites grantii*.—Mr. S. R. Pattison communicates a note on the pyrites deposits in the province of Huelva, in Spain, and Mr. James Geikie the conclusion of his memoir on changes of climate during the glacial epoch. The latter contains a comparison of the glacial deposits of Scotland, Switzerland, Scandinavia, and North America. The other articles in the number are an abstract of the contents of Heer's "Flora Fossilis Arctica," by Mr. R. H. Scott, and an early notice (50 years old) of the occurrence and use of meteoric iron in Greenland.

SOCIETIES AND ACADEMIES

LONDON

Anthropological Institute, March 18.—Dr. Charnock, vice-president, in the chair. M. Letourneur and Dr. Haast were elected corresponding members. Mr. Geo. Harris read a paper on "The comparative Longevity of Animals of different species, and of Man; and the probable causes which mainly conduce to produce that difference." He cited several remarkable instances of longevity both in animals and man, and alluded to the opinions on the subject, both of ancient and modern writers. The influence of climate, air, and food were discussed, and also of domestication and civilisation. The theory of disease in connection more especially with concurrent decay and renovation was inquired into, and some speculations were made as to the effect future scientific discovery, as regards the medical properties both of plants and animals, might have on the question at issue.—Sir Duncan Gibb, Bart., M.D., read a paper on "The Physical Condition of Centenarians." His remarks were founded upon an examination of six genuine examples, in whom he found the organs of circulation and respiration in a condition more approaching to the prime of life than old age. There was an absence of all those changes usually observed in persons reaching 70, and in nearly all the special senses were unimpaired, the intelligence perfect; thus showing, at any rate, the complete integrity of the nervous system. The author's views were opposed to those held regarding the extreme longevity of centenarians.—Dr. Leith Adams exhibited and described a series of stone implements from the island of Fierm; and Col. Fox contributed a note on some stone implements and pottery from St. Brieenne, Normandy.

Entomological Society, March 4.—Prof. J. O. Westwood, president, in the chair.—Prof. Westwood exhibited living specimens of the *Acaris* described by him at the last meeting as *Argas reflexus*, from Canterbury Cathedral, and also another species of the genus found by Dr. Livingstone in Central Africa, which enters the feet of the natives between the toes, causing pain and inflammation.—Mr. S. Stevens exhibited an apparently new species of *Phycita* from near Gravesend, remarkable for its pearly colour and *Crambus*-like form.—Mr. F. Smith read an extract from a further communication from Mr. J. T. Moggridge respecting the storing of grain by ants at Mentone. Mr. Moggridge had confined a colony of the ants in a glass vessel so as to observe their habits, and he was now able to state positively that they fed upon the grain. A detailed account of the observations will be furnished by Mr. Moggridge upon his return to England.—Mr. Müller exhibited galls formed by *Acaris*, of the genus *Phytoptus*, upon the leaves of *Cinnamomum nitidum*, from Bombay, being the first observation of the occurrence of those creatures in India.—Mr. H. W. Bates exhibited a series of species of *Cira-*

THURSDAY, MARCH 28, 1872

THE IRON AND STEEL INSTITUTE

THE Third Annual Meeting of the Iron and Steel Institute was last week held in London, under the presidency of Mr. Henry Bessemer, and has been numerously attended by representatives, not only of the principal iron and steel works in the United Kingdom, but also by those of many of the most important metallurgical establishments on the Continent, which in several instances have sent special delegates to this meeting.

It will perhaps be remembered that the Iron and Steel Institute was founded barely three years ago, and that upon the occasion of the Inaugural Address, delivered by the first president (the Duke of Devonshire), it had then only received the adherence of some two hundred gentlemen connected with the trade; whereas, on this occasion, notwithstanding that the rules of the society only allow the admission of those either practically engaged in the manufacture or application of iron and steel, or connected therewith by their scientific attainments, it has increased so rapidly in this short interval as to number at present about five hundred members, including in this list nearly all the influence and talent associated with the iron and steel industries of Great Britain. It is self-evident, therefore, that its establishment must be regarded as a complete success, such as could not have been expected had it not supplied a tacitly acknowledged previously existing want. That this conclusion is one accepted not only here at home, but also in every part of the world where the manufacture of these metals is carried on, may be considered as demonstrated on the occasion of this last meeting of the Institute, by the attendance of gentlemen connected with the iron and steel trades of France, Belgium, Germany, Sweden, Russia, Spain, and the United States, several of whom, although foreigners, have, we understand, been so impressed with the good service which the Institute is doing to these metallic industries, as to have enrolled themselves on its list of members.

This unexampled success is no doubt in great part due to the fact that the Council of the Institute have conscientiously adhered to the original programme, in not allowing any of what may be termed trade or purely mercantile considerations to interfere with the true objects for which the Institute was from the first established; these objects being, the scientific and practical inquiry into and the open discussion of all subjects bearing directly or indirectly upon the production and working of iron and steel, to provide the members with a means of intercommunication of their ideas and practical experiences, and to supply them with as accurate information as possible as to what is being done in the same direction in foreign countries as well as at home. How far these aims have been attained in practice, may best be judged of by the rapid increase in members, and by referring to the volumes of the Journal already published by the Institute, which, both abroad as well as at home, have been universally admitted to sustain the high standard aspired to

from the first by this young but vigorous institution, and to stand alone in their line, whether regarded from a purely scientific or a practical point of view.

The two annual (London and country) meetings of the Institute may be likened to those of a permanent technical tribunal, before which everything new in connection with iron and steel has to be brought forward, and judged upon as to its merits, after having first passed through the ordeal of cross-examination by the scientific and practical members of the Institute, with the object, as the president tersely expressed it, of sifting out the grain from the chaff; and short as the existence of the Institute has as yet been it has still been long enough to prove how much the iron trade in general, and inventors in particular, may gain by the constitution of such a tribunal.

The most interesting and important feature of the present meeting has been the reports of the committee on machine puddling. The operation of puddling in the conversion of cast into wrought iron is one of so arduous and trying a nature to the workmen that it is daily becoming, in great part owing to the spread of education and the growing desire of men to better their position in society, more difficult to find hands willing to engage in such heavy work; and as it requires long training to make a good puddler, it has now become altogether impossible to obtain a supply of such workmen sufficient to keep pace with the increasing demand for the product; for which reason we find the manufacturer of wrought-iron completely at the mercy of these men, who, besides not ranking very high in the scale of humanity, keep the ironmasters in a perpetual state of terror by their frequent strikes, which, as a rule, do not benefit either party, yet always result in damaging the general iron trade of the kingdom, by driving it abroad and otherwise. This state of things has, as might naturally be expected, given rise to numerous attempts to supersede manual labour in puddling, by machinery, although it may be said, as yet, unsuccessfully; since, notwithstanding that attempts have been made in all directions, and on the most opposite systems, no one of them, when carefully examined into by the Puddling Committee of the Institute, has been considered to fulfil all the conditions requisite to insure its general adoption. When, therefore, at the meeting of the Institute last autumn, in Dudley, Mr. Danks (an American, although born in Staffordshire) declared that he had successfully solved this problem, his announcement was received with considerable incredulity, and he was requested to explain his system before the Institute. To the surprise, yet it may also be added gratification, of all, his explanations, after having been submitted to a severe cross-examination, were considered so far feasible that the members of the Institute unanimously decided upon taking up the matter, and at once sending out a commission (at an expense of some two thousand pounds) to test the system there, with the furnaces and machinery already erected by Mr. Danks, at the Cincinnati Iron-works, but taking with them sufficient pig-iron and other materials from England and Wales to enable them to thoroughly test the system on the large scale, and thereby insure that the process is adaptable to the products we have to treat in this country. After a most patient and painstaking investigation, the three gentlemen who composed this committee—Messrs.

Snelus, Jones, and Lester—reported the system as a complete success, and well suited for the treatment of the iron of this country, an announcement which was received with the greatest interest; and steps were immediately taken to erect similar appliances in England, so that already in the month of February, one of Mr. Danks's furnaces was at work with results which fully corroborated the report of the commissioners, and left no doubt but that the invention must entirely revolutionise this branch of the iron manufacture, doing away with the severe, and it might almost be called degrading, labour of manual puddling altogether, and in other respects producing wrought-iron of a more certain and superior quality to the product obtained from the same pig-iron by the old system.

It is almost impossible to over-estimate the direct and indirect benefits which must accrue to that greatest of all metallic industries, the iron manufacture; and as it might have been years before this invention had asserted itself had it not been taken up so energetically by the Iron and Steel Institute, this may be mentioned as a striking instance of the important results which may be expected from the labours of such a society.

NICHOLSON ON THE GRAPTOLITES

Monograph of the British Graptolitidae. By H. A. Nicholson, M.D., &c. (Edinburgh: Blackwood and Sons.)

IT is with no small degree of satisfaction that we welcome the appearance of the first part of Dr. H. A. Nicholson's *Monograph of the British Graptolites*, the first English essay attempting a clear digest or history of this very difficult and perplexing group of fossils. Dr. Nicholson has, however, for years lived in those regions whose rock masses, life contents, and structure were long since elucidated and rendered classical and famous by the researches of Sedgwick in 1848; and where these organisms are most abundantly distributed. Patient investigation of the great stores of entombed materials at his command, combined with requisite knowledge of zoology, has favoured the author in the preparation of this valuable contribution to our hitherto limited knowledge of these extinct forms of life.

Much has been written upon the Graptolitidae, but in a disjointed manner, by numerous writers since 1727; but Linnæus, in his "Skanska Resa" in 1768, first applied the name "graptolithus" to some or certain allied forms occurring in the Scandinavian rocks. Much controversy has been carried on about this original scalariform type of graptolite; some writers believing it to have been a monoprioidian, others a diprioidian genus. It signifies little now save as matter of history. Since then eighteen genera and ninety species have been established and recognised in Britain alone, and these have been mostly obtained from rocks of Lower Silurian age. Seven species out of the ninety are only known in the Upper Silurian rocks, and four of these are peculiar to that horizon, or do not range lower. The authenticity then of the character of the one and disputed Linnæan form, will do little more after all than add to the literature of the group. This original figure is sufficient to show us that it was a graptolite in

our acceptance of the genus, and doubtless the form looked upon and drawn by the illustrious Swede was *one of millions* contained in the black and slaty rocks over which he travelled; a form, with many others since discovered, and now known to all students of those Silurian rocks which belt the earth from Canada to Britain, Scandinavia, Saxony, and Bohemia, and on to Australia. The historical notice of the Graptolitidae occupies seventeen pages, and forms a compilation of the bibliography of the group, for which all students will gladly thank the author, from 1821-2, when Wahlenberg and Schlotheim advocated their alliance to the Cephalopoda, to Hopkinson's last paper in 1871 (*describing the reproductive capsules*). We have, in fact, a well-digested chronological history, enumerating about eighty notices, and embracing the labour of thirty-five authors.

To study and examine the graptolites *in situ*, or as they occur in the black paper like flaggy shales of the Arenig, Llandeilo, and Caradoc beds, to which they are chiefly confined in Wales, Westmoreland, Scotland, and Ireland, is no small pleasure; but after their stratigraphical position or succession in time is definitely settled in any area to the satisfaction of the physical geologist or stratigraphist, the question of their zoological affinities, or the position they hold in the animal kingdom with relation to modern and existing types becomes one of high importance and value, yet one even now not satisfactorily determined or established. Were they free swimming or floating bodies, in the old Silurian seas, or were they attached like the hydroid Sertulariidae of modern shores and time? These questions are dealt with by the author under two heads: first, *their mode of existence*, and secondly, *their systematic position and affinities*. To our mind the modes of existence of the Graptolitidae have little weight in classification; a knowledge of their intimate structure alone must be the basis of their zoological position in the animal kingdom.

It was natural that the older writers should have referred this extinct group to many divisions which themselves were not then really understood; and they have been placed in no less than six divisions of the animal kingdom.

Modern systematists, however, have referred them to three groups—the Hydrozoa, Polyzoa, and Actinozoa. In 1839 Sir R. Murchison, in his *Silurian System*, placed them with the Actinozoa, assigning their position to the Pennatulidae, and related to the Virgularia of the northern seas. No real analogy however exists between the tubular chitinous fibre of the graptolites, and the calcareous or sclerobasic rod of Virgularia, whose canosarc secretes no external envelope, and where the polypes are not contained in, or protected by, special chitinous thecae. All research also tends to show that the graptolites were free bodies and perhaps oceanic; the structure and condition of the radicle or initial point is conclusive on this point. With respect to their development we as yet know little; but the fact that, as in other Hydrozoa, the reproductive organs were outwardly developed processes of the body wall, strongly allies them to the Hydrozoa. Hopkinson has of late added much to our knowledge of the external reproductive sacs or gonothecae of Diplograpsus.

To Colonel Pollock is undoubtedly due the suggestion of their sertularian affinities through Sertularia and Plumularia, but they certainly are not their fossil representatives.

The author wisely "regards them as a special group of Hydrozoa" unrepresented by any living forms, and forms them into a distinct sub-class.

Chapter II. is devoted to the form and mode of reproduction. This, we think, would have been better placed after the chapter on their special morphology, or prior to Chapter VIII., which is devoted to their geological distribution. We are prepared to admit, however, that much error has arisen from our want of clearly understanding their true history and the mode of their preservation in rocks of such varied physical texture and chemical condition.

Chapters III. and IV. are devoted to the general and special morphology of the graptolites; typical forms being selected in Chapter III., in which the main anatomical features and aspects are recognisable. For this purpose the author has selected the well-known forms of *G. sagittarius*, *G. colonus*, and *Climacograpsus teretiusculus*, and devotes fifteen figures to the elucidation of the monopronidian and dipronidian type of structure.

Chapter IV. embraces thirteen pages and thirty-five figures devoted to the special morphology of the graptolites. We regard this chapter as a condensed history or digest of the labours of European, American, and British graptolithologists. The views and labours of Hall in Canada, Geinitz, Nilsson, and Barrande in Europe, Salter, Carruthers, M'Coy, Hopkinson, Harkness, &c., and the author in Britain, are embodied under the nature of the solid axis, common canal, canosae, cellules, and ornamentation of the polyary.

Space forbids us to do more than notice that in Chapter V. twelve pages and twenty-two figures are occupied by the consideration of chief and special portions of the graptolites, viz. the "radicle or initial point of Hall," and the basal process, the funicle, or non-celluliferous connecting process, largely developed in the Dichograpsi, and the central disc of the Tetragrapsi. Whether these corneous bodies find their analogue in the float of certain oceanic Hydrozoa has yet to be determined.

The chapter upon reproduction and development contains much important matter. The evidence of reproductive organs, however, amongst a group so obscurely preserved as the graptolites must be studied with much care, and deductions received with much caution, but since Hall, in 1858, first drew attention to what he believed were ovarian capsules, Mr. Hopkinson in 1871 confirmed the discovery and description of pyriform gonothecae or ovarian capsules in *Diplograpsus pristis*.

Nicholson had, in 1866, noticed bodies which he believed to be, and referred to, reproductive bodies, and named them *grapto-gonophores*. He, however, had doubts as to their analogy. Mr. Carruthers differed from the deductions of Nicholson, maintaining that these bodies were accidental, or did not belong to the graptolites, although associated or in juxtaposition with them.

Mr. Carruthers first drew attention to and noticed the existence of young forms of graptolites; but Prof. Hall appears to have been the first to make accurate observations upon their development (Grap. of Quebec group, Pl. B, p. 12—19). We, however, as yet know little about this obscure question or point in their history.

The chapter upon the systematic or zoological position of the graptolites is a valuable one, the author taking

and adopting what we believe to be the right view, placing them in the Hydrozoa. This is the first and invariably question of the systematist; the naturalist shirks the question and waits.

It is quite impossible within the limits at our command to discuss the interesting problem of the geological distribution of the graptolites. Although strictly Silurian as regards age, and only occurring in rocks of that period, yet their assignment to the special area which gave birth to them, and from whence they became distributed in space, is a problem yet to be worked out. We believe this has been elsewhere attempted by the author. That the Quebec genera and many species agree in the main with the so-called Arenig or Skiddaw slate forms in Britain is certain, and this is a fact of much interest as a question of distribution. At present we know of no species in the Tremadoc beds, omitting Dictyonema of doubtful affinity; and the statement that the lower Llandeilo flags of Wales are the precise equivalents of the Skiddaw slate of Westmoreland needs confirmation; neither should we hastily accept the generalisation that the Potsdam group in America is upon the horizon of the Skiddaw series, but rather perhaps refer the Quebec and Chazy series to the Arenig or Skiddaw beds of the lake country, where, or in the Llandeilo area in Wales, the graptolites perhaps came first into existence, unless to Canada we refer their birth-place. Homotaxically, however, we require more data. Nine out of fifteen genera are common to Britain and Canada; and this though the Skiddaw slates of Westmoreland, indeed the Skiddaw and Llandeilo rocks and their equivalents, are the graptolitic beds throughout Europe if not the world. The old generalisation as to the dipronidian species occurring in the Upper Silurian is confirmed and borne out by the researches of Nicholson: the unsatisfactory genus Retiolipes alone being found. The sea which deposited the Caradoc rocks saw the last of the compound species, and the physical nonconformity was also a zoological one, especially in hydrozooid life. Indeed only 140 species of all groups of 1,450 known Silurian species, or 10 per cent., are common to rocks of Lower Silurian and Upper Silurian time.

Chapter IX. deals with the generic characters of the radicate group, omitting those of doubtful affinity; the author follows the sectional grouping of Barrande, adopting monopronidian and dipronidian, &c., as modified by Hopkinson.

We look forward with much interest to the part containing full and detailed descriptions of the species. The splendid volume by Prof. Hall and Sir William Logan upon the Canadian species (Report of Progress of the Geological Survey of Canada, 1857, and figured descriptions of Canadian organic remains Decade 2, Grap. of Quebec group) we hope to see equalled if not surpassed by the author of the present valuable memoir. R. E.

OUR BOOK SHELF

Observations upon the Climate of Uckfield. A Meteorological Record for the district from 1843 to 1870, &c. By C. Leeson Prince, M.R.C.S., F.R.A.S. (London: Churchill, 1871.)

WE opened this work expecting to find in it a mere record of the barometric and thermometric observations taken

by an assiduous observer for twenty-seven years. It is this, however, and much more; and Mr. Prince must be congratulated upon having written a very interesting and readable book upon what we fear would, in the hands of most men, be a very dry subject. The observations he has collected show what valuable information might be stored up by many country surgeons, clergymen, and farmers, at little cost of time or money, by adopting a regular system. The parish of Uckfield, Mr. Prince tells us, lies upon an undulatory tract of country situated about midway between the South Downs and the highest point of Ashdown Forest. The upper portion of the town is 200 feet, and the lower 66 feet, above the level of the sea. It is situated on the Horsted beds of the Hastings Sands. The instruments were read every morning at nine o'clock. The annual mean height of the barometer at Uckfield, as deduced from observations extending over seventeen years, was 29.982 in. Mr. Prince gives the mean temperature of winter at Uckfield from all his observations at 38° 96 Fahr.; of spring at 47° 66; of summer at 61° 34, and of autumn at 50° 45. The coldest winter was that of 1845; the warmest that of 1869; the difference being 10° 99. The coldest spring was that of 1845; the warmest that of 1848; the difference, 5° 84. The coldest summer was that of 1860; the warmest that of 1859; the difference being 6° 74. The coldest autumn was that of 1867; the warmest that of 1857; the difference being 6° 22.

Mr. Prince points out that "the mean annual temperature varies 5° 3, viz.: from 51° 93 in 1857 to 46° 62 in 1845, and although at first sight this difference may not appear considerable, yet it is sufficient to exert an enormous influence upon the general character of the seasons, the produce of the soil, and the health of the population. The Registrar-General's interesting returns have fully established the important fact that there is a very intimate connection between temperature and mortality. Whenever the mean temperature falls to 45°, or thereabouts, the number of deaths from diseases of the respiratory organs increases, and should it fall below 40°, death-rate from such diseases is still higher. When a period of intense cold prevails, so that the temperature scarcely rises above the freezing point for two or three weeks, the number of deaths will be found to exceed what takes place during an epidemic of cholera or scarlet fever. But when the mean temperature rises to 55°, there will be an increase in the number of deaths from diseases of the abdominal viscera, and this number will fluctuate as the temperature fluctuates between 55° and 65°. Hence we are informed that the mortality from all causes is least when the temperature is about 50°, which is very little above our mean annual temperature." In this way Mr. Prince deduces important conclusions from statistics, and renders his book much lighter reading than might have been anticipated. He devotes a chapter to the general characters of the months, and then inserts a series of monthly remarks respecting atmospheric phenomena from the year 1843 to 1870, both inclusive. His fifth chapter treats of prognostics of atmospheric changes, and includes a translation of the poet Aratus' "Diosemeia." He remarks very sensibly that with reference to prognostics of seasons, there are very few upon which any reliance can be placed. But the following, of which we can only quote a few, need not, he thinks, be altogether discarded.

From whatever quarter the wind blows at the quarter days, there is a probability of its being the prevalent wind during the ensuing quarter. Whenever the latter part of February and beginning of March are dry, there will be a deficiency of rain up to Midsummer-day. When the foliage of the ash appears before that of the oak, we shall probably have much rain the first half of the summer; but there will be a good harvest-time. When during the spring more swifts than swallows arrive, expect a hot and dry summer. Many other prognostics of change of weather are given, drawn from the habits of mammals,

birds, insects, and plants, some of which are very curious.

The last chapter gives some vital statistics in regard to the population of the country; from which it appears that Sussex is one of the most salubrious counties in England, its death-rate being 1.82 per cent., in which it is surpassed only by the extra-Metropolitan portion of Surrey, the mortality of which is only 1.78; whilst that of Lancashire is 2.78 per cent. Upon the whole we warmly recommend Mr. Prince's book to our readers, and trust that some of them may be induced to commence a similar series of observations. A flora of the district, with the times of flowering of the plants, would, we think, be an interesting addition to Mr. Prince's work.

H. P.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

Circumpolar Land

In a previous letter* I have endeavoured to show that the land surrounding the North Pole is rising in a continuous and definite area. I find that what I there said about the land north of America is very scanty and unsatisfactory, and before proceeding to the next part of my subject, I wish to strengthen it somewhat. Speaking of the eastern part of Melville Island, Captain Parry says one of the *Hæcla*'s men brought to the boat a narwhal horn, which he found on a hill more than a mile from the sea. Sergeant Martin and Captain Sabine's servant brought down to the beach several pieces of fir tree, which they found nearly buried in the sand, at the distance of 300 or 400 yards from the present high-water mark, and not less than thirty feet above the sea level (Parry's Voyage, 1819, 1820, p. 68). Again, "in the north of Melville Island, two pieces of drift wood were found, ten or twenty feet above the present sea level, and both partly buried in the sand" (p. 193). Again, speaking of west of the same island, "The land gains upon the sea, as it is called, in process of time, as it has certainly done here, from the situation in which we found the drift wood and the skeletons of whales" (p. 235).

In Franklin's voyage in 1819, 20, and 21, he mentions having found much drift wood in the estuary of the Copper Mine River. He also picked up "some decayed wood far out of reach of the water" (see his narrative, p. 357). In his second voyage along the Arctic Sea, he describes the coast from the Mackenzie River to the Rocky Mountains as very shallow, and full of shoals and reefs. Inside some of the latter was brackish water, as was also the water in pools at some distance inland; piles of wood were also thrown up far from the coast (see p. 134). While Franklin surveyed the coast westward, Dr. Richardson did the same to the east. He says, "On the coast from Cape Lyon to Point Keats, there is a line of large drift timber, evidently thrown up by the waves, about twelve feet in perpendicular height above the ordinary spring tides." He shortly afterwards mentions that in the Polar Sea, when cumbered with ice, such waves are impossible, and as his journey was in the hottest season, and the sea was then crowded with hummocks, the inference that the drift wood was thrown up by the waves is inadmissible; and the line of drift wood twelve feet above the sea level is only a parallel to the numerous cases we have mentioned. The vast sheet of shallow and brackish water, 140 miles long and 150 broad, which is separated from the Polar Sea by low banks and spits of sand, and is called by Dr. Richardson Esquimaux Lake, formed, there can be little doubt, very recently, as that traveller suggested, a bay of the Polar Sea, and is an example of the formation of huge brackish lakes by a sea which is constantly contracting, such as are so familiar in the eastern borders of the Caspian.

It would be impossible, in the short space at my command, to collect many instances of the same kind that are found in the later Arctic voyages; but I would especially commend the pages of Captain Macleure's and of Sir Edward Belcher's narratives, as containing very striking ones.

The orthodox school of physical geographers generally speak

* See NATURE, vol. v., p. 163.

of Behring's Straits, and the shallow sea about the islands, as an area of depression, but without any authority, so far as I know.

Those barren and desolate islands, so well described by the Russians, bear all the traces of having recently been under water, and the American Birkbeck has proved, beyond much doubt, that the eastern coasts of Asia, including China and Japan, are being upheaved. I find I was forestalled by Pennant in the conjecture of the very recent junction of the White Sea and the Baltic, and I am very glad to quote him as an authority. He says the lakes Sig, Ondar, and Wigo, form successive links from the Lake Onega to the White Sea. The Lake Saima almost cuts Finland through from north to south; its northern end is not remote from Lake Onega, and the southern extends very near to the Gulf of Finland, a space of nearly 40 Swedish or 260 English miles. These, probably, were part of the bed of the ancient Straights (*ist.*) which joined the White and Baltic Seas (Appendix to Arctic Zoology, 23).

In regard to the rise of Spitzbergen, it is curious to find the following passage so early as 1646:—"These mountains (twenty-two mountains of Spitzbergen) increase in bulk every year, so as to be plainly discovered by those that pass that way. Leonin was not a little surprised to discover upon one of these hills about a league from the sea-side, a small mast or a ship, with one of its pulleys still fastened to it; this made him ask the seamen how that mast came there, who told him they were not able to tell, but were sure they had seen it as long as they had used that coast. Perhaps, formerly, the sea might either cover or come near their mountain, where some ship or other being stranded, this mast is some remnant of that wreck." (Account of Greenland by M. La Peyrere in Churchill's Voyages, vol. ii.) Farry, in his account of his journey towards the Pole, 126, also refers to the vast quantities of drift wood stranded on the Spitzbergen coasts above high-water mark.

Having strengthened my former paper by instances of upheaval in other points, and I hope satisfied your readers of the justice of the generalisation about the rise of circumpolar land, it is natural to ask if this remarkable fact is paralleled in any way at the southern pole,—whether we can show that both in the Arctic and Antarctic seas there is a bulging out of the land, and a displacement of the sea at present in progress. Our knowledge of the lands immediately about the southern pole is very scanty; but fortunately we have unmistakable evidence at the various points of those better known austral lands which approach the antarctic seas, from which we may be justified in drawing a sound conclusion, South America, New Zealand, Australia, Tasmania, and Southern Africa.

To begin with South America, I cannot quote a better authority than Mr. Darwin:—

"Everything in this southern continent has been effected on a grand scale: the land from the Rio Plata to Terra del Fuego, a distance of 1,200 miles, has been raised in mass (and in Patagonia to a height of between 300 and 400 feet) within the period of the now-existing sea shells. The old and weathered shells left on the surface of the upraised plain still partially retain their colours.

"I have said that within the period of existing sea shells, Patagonia has been raised 300 to 400 feet; I may add that within the period when icebergs transported boulders over the upper plain of Santa Cruz the elevation has been at least 1,500 feet" (Naturalist's Voyage, p. 171). Again, "M. d'Orbigny found on the banks of the Paraná, at the height of 100 feet, great beds of an estuary shell now living 100 miles lower down nearer the sea, and I found similar shells at a less height on the banks of the Uruguay; this shows that just before the Pampas was slowly elevated into dry land the water covering it was brackish. Below Buenos Ayres there are upraised beds of sea-shells of existing species, which also proves that the period of elevation of the Pampas was within the recent period" (p. 130). So much for the East Coast. Now for the West. Speaking of the Hacienda of Quintero, in Central Chili, he says:—"The proofs of the elevation of this whole line of coast are unequivocal. At the height of a few hundred feet old-looking shells are very numerous." Again, speaking of Northern Chili, he says:—"I have convincing proofs that this part of the continent of South America has been elevated. Near the coast at least from 400 to 500 feet, and in some parts from 1,000 to 1,300 feet, since the epoch of existing shells, and further inland the rise may have been greater. In Peru, about Callao, he also found evidences of rising land; but here we come to one of the horizons where rising and sinking land meet. It is necessary to supplement the account

of Mr. Darwin, I have the authority of Mr. Baxendall for stating that he found numerous skeletons of whales and seals stranded above high-water mark on the coast near Africa, where a tide (as is well known to be the case in all the Eastern Pacific) is almost unknown.

Having satisfied ourselves of the rise of the southern portion of South America, we must now shortly state the reasons for making it very recent. Speaking of the earthquake of 1822, which caused a general upheaval of the land, Mr. Darwin says, "The most remarkable effect of this earthquake was the permanent elevation of the land; the land round the Bay of Concepcion was upraised two or three feet, at the island of Santa Maria (about thirty miles distant) the elevation was greater. On one part Captain FitzRoy found beds of putrid mussel-shells still adhering to the rocks 10 feet above high water-mark; the inhabitants had formerly dived at low-water spring tides for these shells" (p. 310). Again, two years and three-quarters afterwards Valdivia and Chiloe were again shaken, and an island in the Chonos Archipelago was permanently elevated more than 8 feet. At Valparaiso within the last 220 years the rise has been somewhat less than 10 feet, while at Lima a sea beach has certainly been upheaved from 80 to 90 feet within the Indo-human period (*id. passim*). Eighty-five feet above the sea level in an island in the Bay of Callao he found on a sea beach some Indian corn and pieces of Indian thread, similar to those found in Peruvian tombs, a parallel find to that made by Sir Charles Lyell in Scandinavia, which I previously referred to.

Having examined the evidence for South America, we will now turn to the other great southern continent, Africa. I will quote a few passages. "There cannot be the slightest doubt that the upheaval of the country is still going on; for along the whole coast of South Africa from the Cape to Durban Bluff, and still farther north, even as far as Zanzibar, modern raised beaches, coral reefs, and oyster banks may everywhere be seen. At the Iznibuzalungu Caves is such a point, where the rising of the coast is plainly visible, recent oyster-shells are now 12 feet and more above high-water mark. The same can be observed on the whole line of the Natal Coast. Van der Decken has observed the same thing at Zanzibar, and is of the same opinion as myself, viz., that the Eastern Coast is rising early in the present year (*id.*, 1870). I had the opportunity of observing at the Bazanito Islands, about ninety miles north of Inhambane, on the east coast of Africa, a series of raised coral reefs round the island of Marsha containing many living shells and quite recent oyster-banks" (Griesbach, Geology of Natal, Quart. Journ. Geol. Soc. xxvii. part ii. p. 69).

Mr. Griesbach also mentions that he saw implements of early man, which were obtained by Richard Thornton and others in old raised beaches of Natal, near Inanda, and at the mouth of the Zambesi River.

Mr. Griesbach is confirmed by Mr. Stow in his papers on the Geology of South Africa in the same Journal (see vol. xxvii. p. 526 *et seq.*), where bones and teeth are found mixed with shells, quite in a recent state, about Port Elizabeth, &c.

In regard to Tasmania, I quote the following from Mr. Wintle's paper on the Geology of Hobart Town (*Alme Journal*, vol. xxvii. p. 409):—"Until a very recent period in the geological annals of this island, a great portion of what now constitutes the site of this city was under water. This is proved by the extensive deposits of comminuted shells, all of recent species, which are met with for miles along the banks of the Derwent. Some of these deposits are at an elevation of upwards of 100 feet above high-water mark, and from 50 to 100 yards from the water's edge, plainly showing thereby that a very recent elevation of the land has taken place."

In New Zealand the evidence is the same. M. Reclus says the port of Lyttelton has risen 3 feet since it was occupied by the settlers. Mr. Forbes says that proofs of upheaving of the land are even now obvious to any intelligent traveller. Some of these changes have been witnessed by the present generation. Again, in the Middle Island upheaval of the land is observable in a marked manner through the entire length of the western coast from Cape Farewell to Dusky Bay. Some of the most extraordinary changes in these regions have taken place within the last few years.

This has been confirmed by Dr. Haast, who, however, found some signs of depression at the north-western extremity of the lands. In Australia our evidence is ample:—"The north-east, if not the whole of the east coast of Australia, is slowly rising, as proved by the gradual shoaling of the Channel between Hinchinbrook Island and the mainland, due to all appearance neither to

slipping up nor growth of coral water-worn caves, now well above high-water mark in the sandstone cliffs of Albany Island, and those of the mainland opposite, and in the existence along many parts of the coast, especially towards the north of the peninsula, of extensive tracts of level country now covered with sand dunes, bearing a scanty vegetation, stretching inland 10, 15, and 20 miles off, but which once bordered the sea" (Ratray, *Geology of Cape York Peninsula, Australia, Mine Journal*, vol. xxv. p. 297).

"An immense portion of the continent of Australia is known to be uprising. . . . The whole coast round to a distance of several miles inland is covered with recent shells; the drainage of the country is apparently altering. Lakes known to have been formerly filled with salt water are now filling up with fresh or becoming dry. The lagoons near the coast are filled with salt and brackish water, and their banks are filled with marine shells with their colours in many cases preserved. Reefs of rocks are constantly appearing in places where there were none formerly. At Rivoli Bay the soundings have altered so much as to make a new survey requisite. A reef has lately almost closed this harbour. Other reefs have appeared at Cape Jaffa, &c. It would appear that a vast movement is taking place in the whole of the south of Australia. In Melbourne the observations of surveyors and engineers have all tended to confirm this remarkable fact. In Western Australia the same thing is observed at King George's Sound, the same," &c., &c., and so on, for many pages. (See Wood's *Geological Observations in South Australia*, 135-207, and *passim*.)

The facts I have enumerated, which might be almost indefinitely multiplied, are sufficient to prove the position that a very large mass of land near the South Pole which we can examine shows signs of upheaval, and justifies the conclusion that the circumpolar land is rising at both poles, and that there is a general thrusting out of the earth's periphery in the direction of its shorter axis.

I must modify the opinion expressed in a previous paper that the 57th parallel is the southern limit of upheaval in the northern hemisphere. The limit of upheaval is an irregular line. I believe that the district intervening between the two projecting poles, with its focus along the equator, is an area of subsidence. This conclusion I believe to be of crucial importance in solving both geological and meteorological problems.

H. H. HOWORTH

New Zealand Trees

I HAVE been greatly astonished by the perusal of a paragraph on New Zealand timber trees, which appears on p. 14 of the current volume of NATURE (No. 105, Nov. 2, 1871). Almost all that is said, either directly or inferentially in that paragraph is so grossly inaccurate that I cannot understand how such statements found their way into a periodical like yours. In the first place, the Rimu (*Dacrydium cupressinum*), the Matai (*Podocarpus spicata*), and the Totara (*P. totara*), are spoken of as if peculiar to the North Island, whilst the truth is that they are common to all parts of New Zealand. These trees are never "cut down wholesale" for firewood, except perhaps now and then when bush land is being cleared so far from other settlements that transport of the timber to any market is a physical impossibility. The woods enumerated are, Kauri (*Dammarius australis*), and the white pine (*Podocarpus dactyloides*), the principal building timbers of the colony. The Rimu is not "valuable for furniture and all ornamental work," although some choice sections of it look well when carefully polished. Totara and Kauri look better when polished, but their brittleness spoils their usefulness for ordinary furniture work. When I deny that these timbers are "valuable" for cabinet work, I mean that they have not, and never will have, the value which attaches to mahogany, rosewood, walnut, and similar woods. That the Rimu, Matai, and Totara "are none of them Conifere," is news to botanists on this side the world. All these trees are to be found in horticultural collections in England and Scotland, and it is to be regretted that the writer of this paragraph did not acquaint himself with them before he undertook to instruct others as to their botanical characteristics. But the most amazing of all the statements in this paragraph is that about the Rata (*Metrosideros lucida*). This appears to have been quoted from somewhere. I should very much like to know who is responsible for such a monstrous fiction. I can only conceive that its author has confused the Akakura (*Metrosideros scandens*) with the Rata

in his memory—he could never have confused the objects themselves when before his eyes. The whole story of the manner of growth of the Rata is utterly without foundation.

I may take this opportunity of mentioning that the description of *M. lucida* in Hooker's "Handbook of the New Zealand Flora" is inaccurate. The tree is there described as a small one, whereas it grows in the South Island to the dimensions of a large forest tree. Probably Dr. Hooker had to depend on information derived from North Island sources only.

Dunedin, N. Z., January 13

Earthquakes in the Philippine Islands

IN the middle of December, 1871, the volcano Albay in the S.E. of Luzon began to play, and threw out smoke, stones, and lava for several weeks.

The following phenomena have also to be recorded:—
1871.—October 8 and 9, at Pollok on Mindanao, sulphurous springs arose in the neighbourhood.

December 8 to 14, at Kottabato on Mindanao, very heavy earthquakes, which destroyed all the houses.

1872.—January 29, at 7 P.M., at Manila, three slight shocks from E. to W., which I witnessed.

Manila, Feb. 5

A. B. MEYER

Height of Auroras

ALLOW me to suggest the following rules, to be attended to by those who incline to make observations on the heights of auroras:—

1. Observations to be made at the exact hours and half hours, Greenwich mean time.

2. If there is an arch, the position of the apex of its central line should be noted with reference to the stars; or else its altitude should be ascertained carefully, and its azimuth approximately. If the lower or the upper edge of the arch is well defined, give similar particulars respecting it. State the width of the arch; state whether it is regular or not. If it is somewhat irregular, instead of its actual position, give that of an imaginary arch having its average position.

3. If there is any other very conspicuous feature, its position among the stars may be observed; care being taken to describe it sufficiently for it to be recognised in any account from another place. But the position of the corona, or point to which the rays converge, is of no value for determining the height of the aurora, for it is merely an apparent phenomenon.

Observers must not consider themselves tied down to observe on every occasion; any observations, if made in accordance with these rules, may be useful. If they are sent to me, I will endeavour to calculate the aurora's height from them, unless some one else volunteers to take them in hand.

West Hendon House, Sunderland, March 20

Eccentricity of the Earth's Orbit

I SHALL feel obliged if some of your correspondents would inform me if, with the exception of Grant's Physical Astronomy, there is any treatise or encyclopedic article on Astronomy, published in this country before 1864, where the superior limit of the eccentricity of the earth's orbit, as determined by Lagrange or by Leverrier, is given; or even any reference made to the researches of these geometers on the subject.

Edinburgh, March 11

JAMES ELLIS

Barometric Depression

IN Mr. Monck's article on barometric variations in NATURE of 21st inst. there is a serious mistake about the theory of trade-winds. He says the trade-winds would probably extend to the poles were it not that the parallels of latitude become so narrow before reaching them. The trade-winds are east winds; and if, as is certainly the case, the only motive power acting on the earth's atmosphere is the sun's heat, it follows from the law of the conservation of rotation that the total force of the east and west winds must exactly balance each other. This must be the case even were the earth of some other form than a sphere.

JOSEPH JOHN MURPHY

Old Forge, Dunmurry, March 25

FURTHER INVESTIGATIONS ON PLANETARY
INFLUENCE UPON SOLAR ACTIVITY*

1. IN a previous communication by us to this Society, an abstract of which was published in the *Proceedings*, vol. xiv. p. 59,† we showed some grounds for believing that the behaviour of sun-spots with regard to increase and diminution, as they pass across the sun's visible disc, is not altogether of an arbitrary nature. From the information which we then had, we were led to think that during a period of several months sun-spots will, on the whole, attain their minimum of size at the centre of the disc. They will then alter their behaviour so as, on the whole, to diminish during the whole time of their passage across the disc; thirdly, their behaviour will be such that they reach a maximum at the centre; and, lastly, they will be found to increase in size during their whole passage across the disc. These various types of behaviour appear to us always to follow one another in the above order; and in a paper printed for private circulation in 1866, we discussed the matter at considerable length, after having carefully measured the area of each of the groups observed by Carrington, in order to increase the accuracy of our results. In this paper we obtained nineteen or twenty months as the approximate value of the period of recurrence of the same behaviour.

2. A recurrence of this kind is rather a deduction from observations more or less probable than an hypothesis; nevertheless, it appeared to us to connect itself at once with an hypothesis regarding sun-spot activity. "The average size of a spot" (we remarked) "would appear to attain its maximum on that side of the sun which is turned away from Venus, and to have its minimum in the neighbourhood of this planet." In venturing a remark of this nature, we were aware it might be said, "How can a comparatively small body like one of the planets so far away from the sun cause such enormous disturbances on the sun's surface as we know sun-spots to be?" It ought, however, we think, to be borne in mind that in sun-spots we have, *as a matter of fact*, a set of phenomena curiously restricted to certain solar latitudes, within which, however, they vary according to some complicated periodical law, and presenting also periodical variations in their frequency of a strangely complicated nature. Now these phenomena must either be caused by something within the sun's surface, or by something without it. But if we cannot easily imagine bodies so distant as the planets to produce such large effects, we have equal difficulty in imagining anything beneath the sun's surface that could give rise to phenomena of such a complicated periodicity. Nevertheless, as we have remarked, sun-spots do exist, and obey complicated laws, whether they be caused by something within or something without the sun. Under these circumstances, it does not appear to us unphilosophical to see whether as a matter of fact the behaviour of sun-spots has any reference to planetary positions. There likewise appears to be this advantage in establishing a connection of any kind between the behaviour of sun-spots and the positions of some one prominent planet, that we at once expect a similar result in the case of another planet of nearly equal prominence, and are thus led to use our idea as a working hypothesis.

3. We have now a larger number of observations at our disposal than we had in 1866. We had then only the groups observed by Carrington, the positions and areas of all of which we had accurately measured. We have now in addition five years of the Kew observations, for each group of which the positions and areas have been recorded

by us in our previous communications to this society. We have thus altogether observations extending from the beginning of 1854 to the end of 1860, forming the series of Carrington; and observations extending from the beginning of 1866, forming the Kew series, as far as this is yet reduced. We have, in fact, altogether a nearly continuous series, beginning a year or two before one minimum, and extending to the next, and thus embracing rather more than a whole period.

We propose in the following pages to discuss the behaviour with regard to size of the various groups of these two series, as each group passes from left to right across the sun's visible disc. Unfortunately for this purpose, a large number of groups has to be rejected; for, on account of bad weather, we have frequent blank days, during which the sun cannot be seen, and on this account we cannot tell with sufficient accuracy the behaviour of many groups as they pass across the disc. In our catalogue of sun-spot behaviour, we have only retained those groups for which, making the times abscissæ, and the areas ordinates, we had sufficiently frequent observations to enable us to construct a reasonably accurate curve exhibiting the area of the group for each point of its passage across the disc. From these curves a table was then formed denoting the probable area of each non-rejected group at the following heliographic longitudes (that of the visible centre of the disc being reckoned as zero):—

$$-63^{\circ}-49^{\circ}-35^{\circ}-21^{\circ}-7^{\circ}+7^{\circ}+21^{\circ}+35^{\circ}+49^{\circ}+63^{\circ};$$

in fact, giving the area of the group for the ten central days of its progress, and rejecting those observations that were too near the sun's border on either side, on account of the uncertainty of measurement of such observations. We have succeeded in tabulating in this manner 421 groups of Carrington's series, and 373 groups of the Kew series up to the end of 1866, in all 794 groups. In this catalogue the area is that of the whole spot, including umbra and penumbra; and in measuring these areas a correction for foreshortening has always been made, as described in a paper which we presented to this society, and which constitutes the first series of our researches. These areas are expressed in millionths of the sun's visible hemisphere.

4. When we began this present investigation into the behaviour of spots, we soon found reason to conclude that in the case of sun-spots the usual formula for foreshortening is not strictly correct. Perhaps if a sun-spot were strictly a surface-phenomenon, the usual formula might be correct, though even that is doubtful; for the earth as a planet may not impossibly affect the behaviour of all spots as they cross the disc, so as to render the formula somewhat inexact. However this may be, a spot is probably always surrounded more or less by faculose matter, forming in many cases a sort of cylindrical wall round the spot. Now the effect of such a wall would be to allow the whole spot to be seen when at or near the centre of the disc, but to hide part of the spot as it approached the border on either side. A spot thus affected would therefore appear to be more diminished by foreshortening than the usual formula would indicate; and we should therefore expect, if this were the case, that, on the whole, after making the usual allowance for foreshortening, spots would nevertheless be found deficient in area near the borders as compared with their area at the centre of the disc. As a matter of fact we have something of this kind, as will be seen from the following table, in which we have used the whole body of spots forming the catalogue to which we have made allusion.

In this table the first column denotes the heliocentric longitude from the centre of the disc reckoned as zero; the second denotes the united areas at the various longitudes of all those groups from both series, the behaviour

* By Warren De La Rue, D.C.L., F.R.S., Balfour Stewart, LL.D., F.R.S., and Benjamin Loewy, F.R.A.S. Read before the Royal Society, March 14, 1872.

† See NATURE, vol. v., p. 192.

of which we have been able to obtain with accuracy; while the third column exhibits the residual factor for foreshortening, which will bring the areas of the second column into equality with each other.

TABLE I.

Longitude observed.	United areas of all groups at longitude of column 1.	Residual factor for foreshortening necessary to equalise the areas of column 2.
-63	147,508	1'229
-49	156,758	1'156
-35	168,697	1'075
-21	176,417	1'028

+21	178,638	1'015
+35	175,747	1'032
+49	171,140	1'059
+63	162,541	1'115

5. From the above table it appears that the average behaviour of spots, as far as can be judged from the information at present attainable, is not quite symmetrical as regards the centre of the disc. Without attempting at present to enter into an explanation of this remarkable phenomenon, we may point to it as a confirmation of our view previously stated, that most spots are accompanied by a wall-shaped surrounding of facula. Observations show that on the whole the life-history of the facula begins and ends earlier than that of the spot which it surrounds, and that throughout a gradual subsidence of this elevated mural appendage seems to be taking place. But such a diminution of the wall discloses more of the spot itself, and hence the spot-areas, measured on the eastern half of the hemisphere, might be expected, *ceteris paribus*, to be smaller than those observed in the western half, a fact strikingly demonstrated by the above table.

Our present object, however, is not to account for the average behaviour of spots, but rather to investigate the causes or concomitants of a departure from this average behaviour. We have, therefore, in all cases made use of the factors given in the above table as those which, judging by the average behaviour, tend to equalise the

areas that pass the various longitudes. We have called this *earth-correction*, and have limited our discussion to any well-marked behaviour that remains after the earth-correction has been applied.

Let us now divide the whole mass of observations into four portions, depending upon the position of the planet Venus with reference to the earth or point of view. First, let us take each occasion on which the planet is in the same heliographic longitude as the earth, that is to say, when the earth and Venus are nearly in a line on the same side of the sun.

Let us use five months' observations for each such occasion, extending equally on both sides of it; thus, for instance, if the planet Venus and the earth had the same heliocentric longitude on September 30, 1855, we should make use of sun-spots from the middle of July to the middle of December of that year as likely to represent any behaviour that might be due to this particular position of Venus. Let us do the same for all similar occasions, and finally add all the spots thus selected together. We have thus obtained a mass of observations which may be supposed to represent any behaviour due to this position of the planet Venus with reference to the earth or point of view.

Secondly, let us now take each occasion on which Venus is at the same longitude as the extreme right of the visible disc, that is to say, 90° before the earth, and do the same as we did in the previous instance, using five months' observations for each occasion. We shall thus, as before, obtain a mass of observations which may be supposed to represent the behaviour due to a position of Venus 90° before the earth. Thirdly, let us obtain in a similar manner a mass of observations representing the behaviour of sun-spots for a position of Venus 180° before the earth, Venus and the earth being now at exactly opposite sides of the sun; and fourthly, let us finally obtain, in a similar manner, those observations representing the behaviour of sun-spots when Venus is 270° before the earth, being now of the same heliocentric longitude as the extreme left of the visible disc.

These four series of five months each will in fact split up the whole body of observations into four equal parts, the synodical revolution of Venus being nearly twenty months. The following table exhibits these series after the earth-correction has been applied to each. It also represents each series reduced so as to exhibit its characteristic behaviour for an average size of spot = 1000.

TABLE II.

Longitude.	Sum of areas corrected for earth-effect.

	464288	10000	573794	10000	447373	10000	327556	10000

7. We may do the same for the planet Mercury as we have done for Venus, that is to say, we may split up the whole body of observations into four parts, representing the behaviour of sun-spots when Mercury is in the same

four positions with respect to the earth as those which are given for Venus in the above table. Only in this case we must bear in mind that, owing to the eccentricity of Mercury's orbit, this planet will sometimes take a longer,

and sometimes a shorter time to go from one configuration to another. Thus, for instance, we have

Mercury = earth + 0° on March 24, 1854;

Mercury = earth + 90° on May 6, 1854;

and Mercury = earth + 180° on May 29, 1854.

We should therefore take the observations between April

15, 1854, and May 18, 1854, as representing the behaviour of sun-spots due to a position of Mercury 90° before the earth, and so on for other cases. The following table has been constructed on this principle, and it may be regarded as exhibiting for Mercury precisely what the second table exhibited for Venus.

TABLE III.

Longitude.	Sum of areas corrected for earth-effect.							
	(A)		(B)		(C)		(D)	
	Mercury = Earth + 0°		Mercury = Earth + 90°		Mercury = Earth + 180°		Mercury = Earth + 270°	
		1000		1000		1000		1000

	303786	10000	360926	10000	501231	10000	411928	10000

9. If we now examine the two tables for the planets Venus and Mercury, we shall find in them indications of a behaviour of sun-spots appearing to have reference to the positions of these planets, and which seems to be of the same nature for both. This behaviour may be characterised as follows:—the average size of a spot would appear to attain its maximum on that side of the sun which is turned away from Venus or from Mercury, and to have its minimum in the neighbourhood of Venus or of Mercury.

10. The apparent behaviour is so decided with regard to Venus, that the whole body of observations will bear to be split up into two parts, namely, Carrington's series and the Kew series, in each of which it is distinctly manifest. The following treatment will serve to render this effect more visible to the eye.

In Table II., column (A) (Venus = earth + 0°), we have ten final numbers denoting the behaviour of a spot of average area = 1,000 at ten central longitudes as follows:

+54 +42 +23 -4 -30 -61 -49 -25 +1 +49.

Let us take the mean of the first and second of these, the mean of the second and third, and so on, and we get the following nine numbers:—

+48 +32 +10 -17 -45 -55 -37 -12 +25.

Performing the same operation once more, we obtain the following eight numbers, corresponding to the eight central longitudes:—

+40 +21 -3 -31 -50 -46 -25 +7.

In Table V. we have exhibited the results obtained by this process.

11. If we now refer to the table of Jupiter, we find that we cannot detect the same kind of behaviour that we did in the case of Venus and Mercury. We cannot say that such a behaviour does not exist with reference to this planet; but, if it does, it is to such an extent that the observations at our disposal have not enabled us to detect it.

12. The following evidence from a different point of view goes to confirm the results we have now obtained.

We might expect, if there really is a behaviour of sun-spots depending upon the position of Venus, and of the nature herein stated, that the average area of a spot as it passes the central longitude of the disc ought to be

greatest when Venus is 180° from the earth, and least when Venus and the earth are together, and the same ought to hold for Mercury and for Jupiter, if these planets have any influence. Taking the mean of the four central

TABLE V.

Longitude.	Venus (whole series).				Venus (Carrington's series).				Venus (Kew series).				Mercury (whole series).			
	(A)	(B)	(C)	(D)	(A)	(B)	(C)	(D)	(A)	(B)	(C)	(D)	(A)	(B)	(C)	(D)
—49	+40	+48	—18	—118	+8	+30	—10	—160	+117	+58	—27	—46	+28	+45	—50	—12
—35	+21	+46	—20	82	+9	+24	—5	95	+47	+58	—39	—59	+21	+6	—6	—26
—21	—3	+39	—13	43	+1	+24	+10	37	—16	+45	—38	—52	—6	—12	+36	—34
—7	—31	+17	+15	—3	—12	+16	+36	16	—74	+13	—9	—36	—33	—16	+60	—28
+7	—50	—14	+49	29	—23	+2	+53	58	—113	—29	+45	—20	—40	—18	+63	—9
+21	—46	—40	+60	+53	—15	—20	+46	82	—119	—57	+77	4	—28	—20	+43	+19
+35	—25	—50	+34	70	+4	—45	+13	100	—91	—56	+59	+36	—1	—28	+7	+36
+49	+7	—50	—22	+105	+14	—50	—40	+118	—9	—44	+1	+82	+19	—27	—27	+32

areas as giving the best value of the area of a spot its passes the centre, we have for Venus the following results:—

Mean of 4 central areas,

(A)	(B)	(C)	(D)
44741	57426	46068	33995

and the number of groups for these are as follows:—

229	265	150	181
-----	-----	-----	-----

hence the mean area of one group will be,—

195	217	307	183
-----	-----	-----	-----

from which we get (A)=195; mean of (B) and (D)=200; (C)=307; that is to say, A is least, and C is greatest.

Doing the same in the case of Mercury, we get

(A)=204; mean of (B) and (D)=217; (C)=246; and finally, doing the same in the case of Jupiter, we get

(A)=185; mean of (B) and (D)=207; (C)=282; it thus appears that in all these cases the same order is preserved.

13. We leave it to others to remark upon the nature and strength of the evidence now deduced as to a connection of some sort between the behaviour of sun-spots and the positions of the planets Venus and Mercury. We think, however, it must be allowed, that the investigation is one of interest and importance, and we trust that arrangements may be made for the systematic continuance of solar observations in such localities as will ensure to us a daily picture of the sun's disc.

The influence of blank days in diminishing the value of a series of sun-observations is very manifest. We have been able to record the behaviour across the sun's disc of 421 groups of Carrington's series for a total number of 885 groups, and we have been able to record the same behaviour for 373 out of 544 groups observed at Kew. Thus, out of a total of 1,429 groups, we have only been able to record the behaviour of 794. Nor are the records which we have obtained so perfect as we could wish, on account of blank days, which make interpolations necessary. It is therefore of much importance for the future of such researches as the present that there should be several observing-stations so placed that we may reckon on having at least a daily picture of the sun's disc.

It will be easily seen that such observations are very different from experiments which may be multiplied *ad libitum*; for in this case Nature gives us in a year or in ten years a certain amount of information, and no more; while it depends upon ourselves to make a good use of the information which she affords.

It is already universally acknowledged that we ought to make the best possible use of the few precious moments of a total eclipse; but such observations must necessarily be incomplete unless they are followed up by the equally important if more laborious task of recording the sun's surface from day to day.

RHINOCEROSES

THE few species of Rhinoceros which now exist on the world's surface are divisible into two distinct groups, one of which inhabits Africa, the other certain portions of Asia. The Asiatic rhinoceroses are readily distinguishable from their Ethiopian brethren by the presence of incisor teeth throughout life, and by the remarkable folds of the skin. In the African rhinoceroses the incisor teeth are absent, or rather never cut the gums, and the skin is smooth, or, at all events presents scarcely any appearance of the peculiar folds which distinguish the Asiatic species.

Commencing with the Asiatic group, the great Indian rhinoceros (*Rhinoceros unicornis*) is the largest, oldest, and best known species. Of this animal the Zoological Society's Collection contains two adult specimens—a female, purchased in 1850, and a male, presented by Mr. Grote in 1864. But long before the arrival of these animals the large Indian rhinoceros was represented in the Society's Collection by a specimen which died in 1849, and which formed one of the subjects of Prof. Owen's elaborate memoir upon the anatomy of this animal, published in the Society's "Transactions," vol. iv., p. 31.

The habitat of the large Indian rhinoceros is the wooded district called the Terai, which lies along the foot of the Himalayas from Nepal to Bhotan, and thence extends into Assam.

The Sondaic rhinoceros (*Rhinoceros sondaicus*) appears to be very like its larger brother in general conformation, having but one horn on its nose, and the same complicated folds of the skin. It is, however, much smaller in size, and, according to the best authorities, presents certain well-marked cranial characters, which render it easily distinguishable. This rhinoceros was, until recently, supposed to be confined to Java, Sumatra, and Borneo, in which latter island, however, its existence in the present epoch is somewhat problematical.*

Mr. Blyth, however, has recently shown that the one-horned rhinoceros of the Malay peninsula is in all probability referable to this species, and that the rhinoceros which occurs in the Sunderbunds of Bengal is most likely the same animal.

Of the Sondaic rhinoceros, the Zoological Society has

* See Bask in Proc. Zool. Soc. 1855, p. 499, and Fraser, *ibid.*, p. 29.

not yet succeeded in obtaining a specimen, and I am not aware that the animal has ever been brought alive to Europe. It would be of great interest to place a living example of this species by the side of its larger ally in the Regent's Park.

The third Asiatic species of rhinoceros is a very different looking animal from the two previously mentioned, having two horns on its forehead, the smaller of which is situated just above the eye, and the other still farther forward. Its body is, moreover, covered with bristly

SUMATRAN RHINOCEROS

hairs, and there is only one strong, well-marked cutaneous fold of skin on the back, which renders it very unlike its mailed brethren. This animal was until lately supposed to be only found in the Island of Sumatra. Cuvier called

it *Rhinoceros sumatrensis* from this circumstance; and our countryman, Sir Stamford Raffles, who obtained it in that island about the same period, likewise proposed to name it after the country to which he believed it to be

AFRICAN BLACK RHINOCEROS

confined. It has, however, been recently discovered that the Sumatran rhinoceros extends northwards along the whole range of the Malay peninsula, at least as far as Chittagong. The fine female specimen of this rhinoceros now in the Gardens of the Zoological Society of London

was captured a little way south of Chittagong about four years ago. At the time of its capture, it is said to have been quite young, perhaps two years old. Now, however, it is about four and a half feet high, and has probably nearly attained its adult stature; this species being the

smallest of existing rhinoceroses. Singularly enough, at the time this animal was on its way to England, a second specimen of the same species was received by the Zoological Society of Hamburg, and is now living in their gardens in that city. The Hamburg animal is likewise a female, and is said by those who have examined both individuals, to agree in nearly every particular with that belonging to the Zoological Society of London, but to be about one-third smaller.

It must be observed, that although the Sumatran rhinoceros has two horns, it is by no means nearly related to the African two-horned rhinoceros, but has the incisor teeth and other cranial characters of the Indian division of the group.

Of the African rhinoceroses, which constitute the second division of the genus as explained above, many nominal species have been made by naturalists who delight in conferring names upon fragments of horns, and imperfect skulls; but we have not as yet certain evidence of the existence of more than two species, commonly known as the Black rhinoceros and the White rhinoceros.

The Black rhinoceros (*Rhinoceros bicornis* of Linnaeus) has its upper lip long and prehensile. This organ, in fact, forms almost a short proboscis, well fitted for grasping the small branches of trees, upon which it principally subsists. The two horns are not very different in size and length, although the front one is usually longest. The Black rhinoceros is found in Eastern Africa, as well as in the interior of the Cape Colony. In his well-known work on the Nile tributaries of Abyssinia, Sir Samuel Baker describes it as being not unfrequently met with in Upper Nubia. The young male example of this animal obtained by the Zoological Society in September 1868, was captured in this district by the Hammar Arabs, of whose prowess Sir Samuel Baker tells us such wonderful stories. A living example of the African Black rhinoceros has been since added to the collection of the Zoological Society of Berlin; but these two specimens are, we believe, the only individuals of this species that have been brought to Europe, since the days when rhinoceroses were exhibited and slain in the Roman amphitheatres.

The White African rhinoceros is immediately distinguishable from its black brother, apart from the difference in the colour of its skin, by its short upper lip, whence Dr. Burchell, the first scientific traveller who met with it, proposed to call it *Rhinoceros sinus*. It is a grazing animal, feeding chiefly upon grass, and inhabits more open districts than *R. bicornis*. But the most noticeable distinction of the White rhinoceros is the enormous length of the front horn, which in old individuals reaches to three and a half, or even four feet in length, and, after sloping forwards, curves gently backwards towards the summit. The hinder horn, on the contrary, always remains small, and slightly developed. The range of the White rhinoceros in Africa is not very perfectly known. From the inner parts of the Cape Colony it extends probably on to the Zambesi and its affluents. How much farther northwards it may go is uncertain; but, according to Sir Samuel Baker, it is not known in Upper Nubia, where the Black rhinoceros is the only species met with.

No specimen of the African White rhinoceros has yet been brought to Europe, and few additions could be made to the collection of the Zoological Society of London, which would be more acceptable than a young male of this rare and curious animal.

P. L. S.

SCIENCE IN THE NAVY

IT is with great satisfaction that we learn, from a speech made by Mr. Goschen in the House of Commons last week, that the Government proposes a vote of 2,000l.

to Mr. Archibald Smith, Q.C., for great services rendered by him to the Admiralty, not in his professional capacity, but as a man of science whose researches into matters connected with magnetism had been of great service to the Navy and the country. This grant was not proposed as a compensation for Mr. Smith's very laborious services, but as a small mark of the high appreciation the Government had of his eminent scientific services. There was another increase proposed also in aid of the expedition about to be organised under the auspices of the Royal Society to make researches into the depth, temperature, composition, circulation, and distribution of animal life in the Atlantic, Indian, and Pacific Oceans. The total cost to the country, supposing the inquiry to extend over two and a half years, would be about 25,000l., a sum which would not be grudgingly paid in order to secure a vast amount of important scientific knowledge.

The following announcement, with respect to the education of naval officers, will be welcomed with great satisfaction by the scientific public generally:—

"It was proposed that cadets should first go for two years to a Naval College, to master some of the rudiments of their profession, cruisers being attached, so that they might begin to go to sea. At the expiration of or within twelve months they would go out in a seagoing man-of-war, with naval instructors, when they would have for three years a much better education than they now obtain, the same amount of sailing experience being retained. It would then be desirable that they should have six months' teaching preliminary to their examination, when many young officers would ascertain which way their bent lay, and whether they should apply themselves to higher courses of study, for which arrangements could be made, but which would not be entered upon till they had passed the lieutenant's examination. . . . The question that the Government had before them in reference to this subject was how to unite in one establishment all the various branches of naval study which were at present taught in the Royal Naval College at Portsmouth, and in the Naval School of Architecture at South Kensington. At present the Royal Naval College conducted their examinations themselves—that is to say, they first taught and then examined, which was not at all a desirable state of things. It was now proposed to combine the scheme which he had described as regarded the education of the young officers with one for the education of the commissioned officer, and also to make better arrangements for the education of the Engineer and Marine officers. In order to carry out these objects it was proposed to found a Royal Naval College at Greenwich, where all branches of a general naval education would be taught, and to do so upon a scale which would be calculated greatly to raise the tone of our naval officers. In the first place there would be received in the College sub-lieutenants, who would be kept there for six months before their passing their general examination, and also naval officers. It was proposed that after the sub-lieutenants had passed their examinations and had been a short time at sea, those who chose to avail themselves of it should have an opportunity accorded to them of pursuing a higher course of study, of which half-pay officers might also avail themselves, and the establishment being so near London they should be able to offer a better course of study, under more able professors, than would be possible to give at Portsmouth. But, in addition to thus offering an education of this description to the young and to the commissioned officers who now went to Portsmouth, they trusted to be able to make arrangements with regard to the education of Engineer officers. At present these latter officers were all brought up in our own yards, which they entered at about fifteen or sixteen years of age, and in which they remained for four or six years as Engineering apprentices, and at the end of the fourth year three were selected to go to the School of Naval

Architecture at South Kensington. In the same way, from a certain number of shipwrights' apprentices three or four were also selected every year to go up and study at the latter school. As regarded the Engineers, it was proposed that not merely three or four out of the thirty should be sent every year to South Kensington, but that all of them, after having been four years in the yards, should have the advantage of going through a course of one year's education at Greenwich, which should include all the higher branches of engineering education, such as metallurgy and chemistry. It was further proposed to take a similar course with reference to the shipwright's apprentices, but only as regarded a limited number, who would have an opportunity of studying naval architecture at Greenwich. The South Kensington School would be removed to Greenwich. . . . With regard to the cadets, it was not proposed that they should go to Greenwich. No definite arrangements had as yet been proposed with reference to them, but that there was no great hurry in the matter, because in future they would not be taken under fifteen years of age, and it would be as well to wait until those who had entered at thirteen had attained the latter age before new arrangements were entered into with regard to them."

We heartily congratulate the Government on this commencement of a higher scientific instruction of officers of the Navy, and trust that the course thus commenced will be persisted in.

NOTES

THE Royal Commission on Scientific Instruction and the Advancement of Science have, we are informed, concluded their inquiry into the scientific instruction afforded in training colleges and elementary schools, and in the science classes of the Science and Art Department.

THERE will be an election to a Natural Science Fellowship in Exeter College, Oxford, on Wednesday, June 19. The examination will be in Biology. The Fellow elected will be required to reside and take part in the instruction of the College. The election will take place under the conditions of the special ordinance of the College with regard to residence. The Fellow elected under the ordinance will be subject in all other respects to the Statutes of the College. The examination will probably begin on Tuesday, June 11, and no person can be admitted as a candidate who has not passed all the examinations necessary for the degree of Bachelor of Arts in the University of Oxford, or been incorporated as a graduate in the University. Candidates are requested to make application by letter to the rector on or before June 1.

THE examinations for Scholarships in Natural Science, which have recently been held at Clare and at Emmanuel College, Cambridge, have both terminated without an election being made. The reason of this is that at neither of the colleges did candidates present themselves, whose attainments, in the opinion of the examiners, entitled them to receive the distinction. The number of competitors was but small in each case, in one three only.

THE Vice-Chancellor of the University of Cambridge has promulgated the text of a memorial addressed to the University upon the subject of higher education, and adopted at a public meeting at Birmingham. It is similar to the memorials addressed upon the same subject from Rochdale, Leeds, Crewe, and the North of England Council for the Education of Women, and the prayer of the memorial is that a Syndicate be appointed to investigate the subject, and to inaugurate such means as would produce—firstly, a standard of excellence in the departments of literature, science, and art, fixed by some universally recognised authority, and attainable by students of this class, which would secure for their studies the definiteness and thoroughness that are so much needed; secondly, an opportunity, offered to all

who might be inclined to take advantage of it, of bringing their acquirements to the test of an examination; thirdly, the command of teaching power of a high order for the benefit of those who might wish to place themselves under instruction.

PROF. HUXLEY is, we learn from the *Times*, the favourite candidate for the rectorship of St. Andrew's University.

THE following are the probable arrangements for the Friday evening meetings at the Royal Institution after Easter:—April 12, Mr. John Morley, "On Rousseau's Influence on European Thought;" April 19, Mr. Vernon Harcourt, F.R.S., "On the Sulphurous Impurity in Coal Gas and the means of removing it;" April 26, Prof. Blackie, "On the Genius and Character of the Modern Greek Language." May 3, Wm. Spottiswoode, Treas. R.S.; May 10, N. Story-Maskelyne, F.R.S., "On Meteoric Stones;" May 17, Prof. Abel, F.R.S.; May 24, Prof. Clifford, "On Babbage's Calculating Machines;" May 31, Mr. E. J. Poynter, A.R.A. June 7, Prof. Odling, F.R.S. And the following lecture arrangements are announced:—Dr. Wm. A. Guy, F.R.S., three lectures, "On Statistics, Social Science, and Political Economy," on Tuesdays, April 9, 16, and 23; Mr. Edward B. Tylor, F.R.S., six lectures, "On the Development of Belief and Custom amongst the Lower Races of Mankind," on Tuesdays, April 30 to June 4; Prof. Tyndall, F.R.S., nine lectures, "On Heat and Light," on Thursdays, April 11 to June 6; Mr. R. A. Proctor, five lectures, "On the Star Depths," on Saturdays, April 13 to May 11; Prof. Roscoe, F.R.S., four lectures, "On the Chemical Action of Light," on Saturdays, May 18 to June 8.

PROF. THISELTON DYER is about to deliver a course of lectures on flowers and fruits to the Royal Horticultural Society, with the following titles:—Thursday, April 11, "Flowers: their common plan of construction." April 25, "Flowers: the variety in their forms, and how brought about." May 9, "Flowers: their colours and odours." May 23, "Fruits: their structure." June 6, "How seeds are sown in Nature." June 20, "Flowers and Fruits under cultivation." The lectures will commence at 3 P.M.

M. SCHIMPER, the celebrated botanist and paleontologist, is the only one of the old professors in the French University of Strasburg who has consented to continue to hold his post under the German rule. M. Schimper is a Frenchman by birth and descent, and had been offered a superior position elsewhere by the French Government.

M. PRILLIEUX, the French botanist, having declined to continue an honorary Associate of the Leipzig Leopold Academy of Natural Science, some German professors call upon their countrymen to return the "brevets" they have received from French scientific bodies. But it is satisfactory to see Dr. Virchow coming forward to warn his colleagues against imitating such a bad example.

AN ingenious patent is now being worked, by which leather for the sides of boots and shoes is rendered impervious to wet and damp by exhausting the air from the pores of the leather, and filling them up with a substance which unites with and adheres to the fibre, thereby strengthening without impairing the elasticity of the material. It is stated that the patent, known as "Fanshawe's Waterproof Leather," is not only likely to be largely employed for the purpose to which we have referred, but that when asphaltic pavement becomes more general, it will be possible to shoe horses with a material as hard as the asphaltic itself, and which will prevent them slipping.

A NOVEL and most interesting experiment in the field of elementary instruction has just been resolved upon in Saxony. Hitherto, as everywhere else, so in that small but highly-developed kingdom, the youth of the lower orders, upon being

apprenticed to a trade, have been left at liberty to forget the little they learnt at school. Attendance at Sunday schools and evening instruction provided by the State and charitable societies were perfectly optional. By a law just passed this liberty is abridged, and compulsory attendance at evening schools exacted for a period of three years. This is, we believe, the first time in the annals of the world that an attempt has been made by a State to extend the education of the humbler classes beyond the merest rudiments, and after they have entered upon the business of life. Saxony, already the best taught portion of Germany, will by the new law be more than ever in advance of her sister States.

It has been necessary to remove the Parliamentary copies of the Imperial standards, in consequence of the wall of the Palace at Westminster, in which they were immured, having been pulled down in order to form an entrance to the refreshment rooms. On the 7th of March, 1872, in the presence of the President of the Board of Trade and five other public functionaries, the standards were deposited in their new resting place in the wall on the right-hand side of the second landing of the public staircase, leading from the lower waiting-hall up to the Commons' Committee Room. One alteration has been made. When the standards were originally immured, a brass plate was fixed upon the wall bearing the following inscription in old English letters:—"Within this wall are deposited standards of the British yard and the British pound weight, 1853." The word "measure" has now been inserted after "yard."

In another column will be found an article on the recent meeting of the Iron and Steel Institute, referring, among other matters of interest, to the new puddling machine. We learn that an agreement has been entered into between Mr. Danks, the inventor, and a combination of iron manufacturers representing the different districts, whereby the latter undertake to have 200 furnaces on his plan put up within six months, and in consideration of his permission to do so, to pay him 50,000*l.* at that time, whether the furnaces are in operation or not. This step, which adds something like 450 furnaces to our producing power, will effect such a revolution as has never before occurred in the history of this branch of industry, and it is the more to be wondered at when it is remembered that, till July last, it was thought that hand-puddling must for ever continue, every machine to do away with it having, before that, entirely failed.

THE *Swiss Times* says that the late Professor Pictet-de-la-Rive has left the whole of his remarkable palæontological collection to the Museum of Natural History, and the greater part of his valuable scientific library to be divided between the Academic Museum and the Library of the city of Geneva.

WE learn with regret of the death, at his plantation, not far from Vera Cruz, of Dr. Charles Sartorius, a gentleman well known in the United States and Europe as a naturalist and meteorologist. Few students of the zoology and botany of Mexico have failed to become acquainted with the labours of the doctor, as shown by the numerous specimens sent to the museum of the Smithsonian Institution and to the American Entomological Society, &c.

THE French Minister of Agriculture and Commerce has ordered the institution at the Central School of Arts and Manufactures at Paris of a new course of lectures to be devoted to the higher teaching of agriculture.

THE Annual Meeting of French *savants*, held at Paris under the auspices of the Ministry of Public Instruction, will commence on Monday, April 1, at the Sorbonne, and continue on the three following days.

WE regret to learn that the proposed Dredging Expedition of the *Norna* is postponed, one of the party being seriously

ill, and her owner somewhat unexpectedly having to join his regiment in May instead of autumn. He is anxious to employ a vessel large enough to carry a good stock of fuel for a donkey engine, to save time and labour, and the *Norna* being small for this, and for carrying a steam launch, as is also to be desired, Mr. Marshall-Hall will, in all probability, part with her. If he is successful in organising the more extensive undertaking now proposed, he fully expects to contribute very interesting observations to marine science, and to investigate several chemical questions, besides the zoological work.

PROF. PEPPER, who has done good service in working some of the more popular and easily-illustrated departments of science at the Polytechnic, is about to leave that Institution, and to start an exhibition on his own account at the Egyptian Hall, Piccadilly, in conjunction with Mr. T. W. Tobin.

PROF. LUTHER has discovered a new planet (No. 118) of the 11th magnitude. The discoverer suggests the name "Peitho."

AT the meeting of the Royal Geographical Society, held on Monday evening last, Mr. W. Giffard Palgrave read a paper, detailing a journey made by him during his late residence as Consul in Asia Minor. He began by giving a rough account of the general divisions of that region, confining himself more particularly, however, to that tract of country consisting of tableland, formerly known as Armenian, and where, moreover, the Tigris, Euphrates, and other important rivers take their rise. Many observations made of phenomena in the neighbourhood of the range of mountains known as the Kolat Tagh all tended to show beyond doubt that at some period or other glaciers must have formed and existed in large quantities in the immense tracts of mountains, though at the present time the climate is too genial to allow the snow to remain even on the ridges and peak throughout the year. A short insight was afforded into the volcanic features of the place, and also into the mineralogical formation of the soil. From this it appeared that mines, if only persons were found enterprising enough to work them, might be opened which would yield a surprising amount of lead and a considerable quantity of silver, and would most likely prove very lucrative.

THE educational importance of our large schools, not only to their actual pupils but to the inhabitants of the surrounding neighbourhood, is being happily illustrated at Taunton. An able lecture on "The Theory of Musical Tone," was delivered last week to a large audience in the College School Dining-hall by Mr. E. B. Tylor, F.R.S. It was largely illustrated by experiments, and the valuable apparatus was left behind him by the lecturer as a present to the School. It is hoped that other lectures on Science, Art, and Literature, will succeed; and that gentlemen of eminence will be found to aid, by their presence and teaching, so praiseworthy an attempt. For some time past the Botanical Lectures at the School have been attended not only by the pupils, but by a considerable number of strangers; and a class of forty students will present themselves for the approaching South Kensington Examination in Botany. There is already a small Botanical Garden, well furnished and laid out, which will be largely increased when the funds of the School permit. *O, si sic omnes!*

MR. FAIRGRIEVE, successor to Mr. George Wombwell, is about to sell by auction his well-known menagerie. The catalogue comprises 186 lots, and includes a large number of monkeys, ten lions and lionesses of various ages, a tiger and tigress, a male and female elephant, three boa constrictors, and a large number of other animals, and apparatenances. The sale will take place at Edinburgh, and will commence on April 9, unless the whole menagerie is previously disposed of by private contract.

GENTLEMEN interested in the improvement of Geometrical Teaching may obtain a copy of the Association's Second Annual

Report (referred to in last week's NATURE) on application to the Hon. Secretaries, King Edward's School, Birmingham, or to the London Local Secretaries, Mr. C. W. Merrifield, F.R.S., South Kensington, and Mr. K. Tucker, University College School.

MR. I. LOWTHIAN BELL read a paper at the Institution of Civil Engineers on Tuesday evening, March 18, "On the conditions which favour and those which limit the Economy of Fuel in the Blast Furnace for Smelting Iron." A discussion on the paper was taken at the following meeting on Tuesday evening last.

MR. ALFRED SMEE, F.R.S., has in the press a volume entitled *My Garden*, in which he gives a complete description of his experimental garden at Beddington, in Surrey, and details the results of his experience in the culture of flowers and fruit: of these nearly 700 species and genera are described. The volume also treats generally of the natural history, geology, and antiquities of the neighbourhood. It is illustrated with about 1,000 wood engravings, executed expressly for the work. The volume will be published by Messrs. Bell and Daldy.

ANNUAL ADDRESS TO THE GEOLOGICAL SOCIETY OF LONDON, FEB. 16, 1872

By J. PRESTWICH, F.R.S., PRESIDENT

IN looking at the labours of the Society during the past year, it is satisfactory to notice the same activity, the same wide range of subjects as ever, and the same independence of research for truth's sake which there ever should be. But, though good work has been done in special branches and the technical details of Geology, not so much progress has been made in its higher problems. I would, however, direct your attention to the steps made in grouping our volcanic rocks, and in the determination of the fauna of our Cambrian strata, which proves to be so much larger and richer than was anticipated a few years back. Both these subjects are in able hands, and cannot fail to yield important results, the latter especially in aiding to settle that interesting question—the true line of division between the Silurian and the Cambrian formations. On the subject of denudation and river-action, we have also had several excellent papers, and look forward with interest to the further development of the many original views which they have put before us.

The great question of the history of our globe during the Quaternary period seems also to be advancing towards more completeness. Many able observers, both in and out of our own Society, are engaged upon the subject, and various scientific periodicals and publications of our local societies are rich in contributions bearing upon this interesting subject. There is no more wonderful chapter in the earth's history than that which embraces the phenomena connected with the prevalence of great and exceptional cold immediately preceding our time,—the first dim appearance of man—his association with a race of great extinct Mammalia belonging to a cold climate—the persistent zoological characters of the one, so far as we have yet gone, in opposition to the variable types presented in geological time by the others—the search for connecting links, and the measure of man's antiquity,—all of which constitute theoretical problems of the highest interest, and are now occupying the attention of geologists of all countries. Allied also to this subject are the great questions relating to the form of our present continents—the elevation of the land—the origin of valleys and plains—and of all that which prepared this globe for the advent of man.

But while treating of these abstract and philosophical questions, geology deals also with the requirements of civilised man, showing him the best mode of providing for many of his wants, and guiding him in the search of much that is necessary for his welfare. The questions of water-supply, of building materials, of metalliferous veins, of iron and coal-supply, and of surface-soils, all come under this head, and constitute a scarcely less important, although a more special branch of our science than the paleontological questions connected with the life of past periods, or than the great theoretical problems relating to physical and cosmical phenomena. Looking at this triple division of geology, and seeing that the first, or applied geology, is, as it were, only

incidental to our general studies, and therefore not often the topic of our discussions, notwithstanding its practical importance, I propose on this occasion to say a few words in connection with the two momentous subjects which, during the last few years, have been made the objects of investigation by two Royal Commissions, on both of which the geological questions have received much and careful consideration. I shall here restrict myself to the more special geological bearings of the subject, extending them, however, in some directions beyond the scope of the original inquiries, and refer you to the Reports and Minutes of Evidence themselves for the many valuable economical questions and practical details which are there discussed.

Our Springs and Water-supply.

The site of a spring or the presence of a stream determined probably the first settlements of savage man; and his civilised descendants have continued, until the last few years, equally dependent upon like conditions—conditions connected first with the rainfall, and, secondly, with the distribution of the permeable and impermeable strata forming the surface of the country. Under ordinary circumstances, few large towns have arisen except where there has been an easily accessible localised water-supply, and where the catchment-basin on which depends the volume of the rivers has been large, and permeable strata prevail. Take, for example, London. Few sites could be more favourable in every respect. Beneath it are strata rich in springs, while at a distance there is that large development of those massive permeable strata so necessary to maintain a sufficient and permanent flow in our rivers. As the conditions exhibited in the London basin afford all the illustrations we need for our subject, I will confine myself in this address to that area alone.

London north of the Thames stands on a bed of gravel, varying in thickness from ten to twenty feet in round numbers, and overlying strata of tenacious clay from 100 to 200 feet. The former being easily permeable, the rain falling on its surface filters through it, until stopped by the impermeable London clay, where it accumulates and forms a never-failing source of supply to the innumerable shallow wells that have been sunk all over London from time immemorial, and which for centuries constituted its sole water-supply. Not only does it form an easily accessible underground reservoir, although of limited dimensions; but where the small intersecting valleys cut down through the bed of gravel into the London clay, a portion of the water in this reservoir escapes at the junction of the two strata, and gives rise to several springs formerly in much repute, such as those of Bagnigge Well, Holywell, Clerkenwell, St. Chad's Well, and others.

The early growth of London followed unerringly the direction of this bed of gravel, eastward towards Whitechapel, Bow, and Stepney; north-eastward towards Hackney, Clapton, and Newington; and westward towards Chelsea and Kensington; while northward it came for many years to a sudden termination at Clerkenwell, Bloomsbury, Marylebone, Paddington, and Bayswater; for north of a line drawn from Bayswater by the Great Western station, Clarence Gate, Park Square, and along the north side of the New Road to Euston Square, Burton Crescent, and Mecklenburg Square, this bed of gravel terminates abruptly, and the London clay comes to the surface, and occupies all the ground to the north. A map of London, so recent as 1817, shows how well-defined was the extension of houses arising from this cause. Here and there only beyond the main body of the gravel there were a few outposts, such as those at Islington and Highbury; and there habitations followed. In the same way, south of the Thames, villages and buildings were gradually extended over the valley-gravels to Peckham, Camberwell, Brixton, and Clapham; while, beyond, houses and villages rose on the gravel-capped hills of Streatham, Denmark Hill, and Norwood. It was not until the facilities were afforded for an independent water-supply by the rapid extension of the works of the great water companies, that it became practicable to establish a town population in the clay districts of Holloway, Camden Town, Regent's Park, St. John's Wood, Westbourne, and Notting Hill.

On the outskirts of London a succession of villages grew up for miles on the great beds of gravel ranging on the east to Barking, Ilford, and Romford—on the north, following the valley of the Lea to Edmonton and Hoddesdon; and on the West, up the Thames-valley to Ealing, Hounslow, Slough, Hammer-smith,

* Royal Commission on Water Supply, appointed April 1867. Report of the Commissioners and Minutes of Evidence and Appendix, June 1869.
 † Royal Commission on Coal Supply, appointed June 1866.
 ‡ Reports of the Commissioners, Minutes of Evidence, Appendix, July 1871.

and beyond; whereas, with the exception of Kilburn, hardly a house was to be met with a few years since between Paddington and Edgware, or between Marylebone and Hendon; and not many even between the New Road and Highgate and Hampstead. As a marked case of the excluding effects of a large tract of impermeable strata close to a great city, I may mention the denuded London-clay district extending from a mile north of Acton, Ealing, and Hanwell, to Stanmore, Pinner and Ickenham, near Uxbridge. With the exception of Harrow (which stands on an outlier of the Bagshot Sands), and Perivale, and Greenford (on outliers of gravel), there are only the small villages of Northolt and Greenford Green. In the earlier edition of the Ordnance Maps, there was a tract of ten square miles north and westward of Harrow within which there were only four houses. Yet the ground is all cultivated and productive. But immediately eastward of this area, and ranging thence to the valley of the Lea, the ground rises higher, and most of the London-clay hills are capped by gravel of an older age than that of the London valley, and belonging to the boulder-clay series. On these we have the old settlements of Hendon, Stanmore, Finchley, Barnet, Totteridge, Whetstone, Southgate, and others.

There is yet another very common source of well-water supply from beds of gravel directing population to low sites in valleys, which is this. Everywhere on the banks of the Thames and its tributaries there is a lower-lying bed of valley-gravel or of rubble on, and often passing beneath, the level of the river. This bed is supplied with water both by rain falling on it, by springs thrown out from the adjacent hills or by the drainage from those hills and in places by infiltration from the river, when, from any cause, the line of water in the gravel falls below that of the adjacent river; while, on the other hand, the surplus land-supplies find their way direct and unseen, from the bed of gravel to the river. A great part of London south of the Thames, Westminster, Battersea, and a number of towns up the Thames, as Hammersmith, Brentford, Eton, Maidenhead, and others, together with Newbury and several villages on the Kennet, also the towns of Ware and Hertford on the Lea, have this shallow well-supply. A great many towns and numberless villages along most of our river-valleys all through England, and on whatever formation situated, are dependent on this superficial source of supply, a supply much more permanent than the other shallow well-supplies, in consequence of the outside aid from springs and rivers. It is, however, only in case of exceedingly dry seasons or of excessive pumping, that the supply requires to be supplemented by the river-waters. As, in ground of this description, the land-water is generally dammed back by the stream, the level of the water in the wells, which are always shallow, varies with the level of the water in the streams, rising and falling more or less with them.

A few of the higher London-clay hills in the neighbourhood of London are also capped by outliers of the Bagshot Sands, as, for example, Harrow, Hampstead, and Highgate, all of which are sites of old habitations. The sands at these places attain a thickness from 30 to 80 feet, are very permeable, and afford a sufficient water-supply by means of wells to a limited population. A number of well-known small springs are thrown out at the contact of the sands and the clay on the slopes just below and around the summit both of Highgate and Hampstead Hills. In some instances, owing to the presence of iron in the sands, they are slightly chalybeate. When the Bagshot Sands, further westward of London, attain their fuller development of from 300 to 400 feet, the depth to the water-level at their base becomes so great that the upper porous beds are left high and dry, and form uncultivated wastes, such as Bagshot Heath, Frimley Heath, and others; but on the outside of this area, where the sands become thinner, and the water-level more within reach, we find a number of villages, such as Englefield Green, Sunninghill, Bracknell, Wokingham, Alderstone, Esher, Weybridge, Woking, &c. There are also some thin subordinate beds of clay in the middle of the series which hold up a sufficient quantity of water for small local supplies, and give rise to small streams in the valleys of the Blackwater and of Chobham. The running nature of portions of these sands, and the presence of beds of ferruginous and green sands, often interfere much with the construction of deep wells, and the quantity of the well-water; and, externally, the mixed clay-and-sand character of the upper beds of the London clay fails to give any good retaining-line for the water, which therefore rarely issues as springs, but oozes out from the general surface of the intermediate spongy mass.

The 70 to 100 feet of sands and pebble-beds belonging to the lower tertiary strata under the London clay, and overlying the chalk, are also very permeable, and being intercalated with some beds of retentive clay, they give rise to one or two levels of water, affording wherever these strata form the surface, as at Blackheath, Bexley, Chislehurst, and Bromley, a moderate water-supply to shallow wells. Where these sands dip under the London clay, and only present a narrow belt on the surface, a small valley is commonly formed into which the London-clay hills drain on the one side, and on the other the chalk dammed back by the Tertiary strata throws out its springs, and the sands are thus kept charged with water up to a short depth from the surface. As instances of the many places whose sites have been determined by these favourable circumstances, I may name Croydon, Beddington, Carshalton, Sutton, Cheam, Ewell, the villages between Epsom, Ashstead, and Leatherhead, to Guildford, and again between Old Basing and Kingsclere.

But besides furnishing a supply by ordinary wells to a number of villages on their line of outcrop, the Lower Tertiary sands have of late years contributed to the metropolitan supply, as well as to the supply of those adjacent districts where the surface is formed of tenacious clay, and water is scarce, by means of artesian wells. For along the line of country just named, and along a more irregular belt on the north of London, these sands pass beneath the London clay, so that the water they receive from rain and springs on the surface, passes underground, where it is prevented from rising by the impermeable superincumbent clay; consequently, as there is no outlet for the water below ground, these sand-beds are filled with water along their whole underground range, between their outcrop in Surrey and that in Hertfordshire.

I need not dwell here upon the constructions of Artesian wells, which have been explained by Héricart de Thury, Arago, Degoussé and Laurent, Burnell, Hughes, myself, and others, beyond offering a few explanatory remarks on this particular case, which we shall also have to bring to bear upon the origin of springs.

The surface of the ground at the outcrop, just referred to, of the Lower Tertiary sands is about 100 ft. above the level of the Thames, whilst under London the sands are at a depth of from 100 ft. to 220 ft. below that level, thus forming the shell of a basin from 200 ft. to 300 ft. deep, the centre of which is filled with a depressed mass of impermeable clay. There is, however, a notch in the lip of the basin, where it is traversed by the Thames, at Deptford and Greenwich, which is at a lower level of 100 ft. than the rest of the rim. Below this level, as there is no escape for the water, the strata are naturally perpetually water-logged; and if any water is withdrawn from one part, it is, owing to the permeability of the strata, at once replaced from adjacent parts of the same strata. Early in the present century, bore-holes were made through the overlying London clay to the sands at depths of from 80 ft. to 140 ft., and the water from these deep-seated springs rose at once to a height of several feet above the level of the Thames, where it tended to maintain itself, and thus form, in the lower-lying districts, permanent natural fountains. But the ease and facility with which this abundant supply was obtained, led to the construction of so great a number of such wells that a time soon came when the annual rain outfall no longer sufficed to meet the demand, or, rather, it could not be transmitted fast enough to the central area of abstraction to replace the out-draught. The consequence was that, after some years, the water ceased to overflow, and the line of water-level has gradually sunk at London, until it now stands some 70 ft. or 80 ft. beneath the surface level. This, however, is not the case at a distance from London; and in many parts of Middlesex, and more especially in Essex, where Artesian wells are common, they have been found of very great service.

In order to supply the deficiency thus caused in the Lower Tertiary sand, most of the Artesian wells in London have of late years been carried down into the underlying chalk, which also extends beneath London at depths of from 150 ft. to 250 ft. Both formations are permeable, but in different ways. On both the rainfall is at once absorbed, but the transmission of it is effected in different ways. Through the sands it filters at once; but not so with the chalk. A cubic foot of the latter will hold two gallons of water by mere capillary attraction; but it parts with this with difficulty. Still in time it finds its way through the body of the chalk, aided by the innumerable joints, fissures, and lines of flints by which this formation is traversed; and, when once under the line of saturation,

tion, the water in these fissures circulates freely. This line of saturation is governed in this as well as in all other permeable formations, by the level of the lowest natural point of escape, which is either the coast-line if near, or the nearest river-valley. Below these levels permeable strata are always charged with water; consequently under London the chalk is everywhere water-bearing; but as the Lower Chalk is more compact than the Upper, and is less fissured, especially when covered by other strata, and as the more compact water-logged chalk delivers its charge with extreme slowness, it is not until a fissure is met with that a free supply of water is obtained. Further, as there is no law regulating the position of the fissures, the depth to which the chalk has to be traversed before meeting with a free supply of water is quite uncertain. It is a question of probability depending upon meeting with a fissure sooner or later—10 to 15 feet have sufficed in some of the deep London wells, whereas in others it has been necessary to sink to a depth of from 100 to 200 feet or more before hitting on the necessary fissures. Large as this supply is, the same causes which have operated in the case of the sands have told also on the chalk supplies (and, no doubt, there is some community between the two), and the great demands on it have occasioned a similar lowering of the water-line. At the same time this line also remains unaltered at a distance from London, and as with Tertiary Sands the mass of the chalk beneath intersecting the level of the river valleys remains constantly charged with water. Ordinary wells, therefore, sunk below this line of saturation into the chalk where it comes to or near the surface, are capable of yielding very large quantities of water. More than seven million gallons daily are in fact now so obtained from the chalk on the south-east of London.

Numerous and useful as the London Artesian wells are, they sink into insignificance when compared with the application of the same system in Paris. Our deepest wells range from about 400 to 500 feet, and the water comes from the chalk hills at a nearest distance of from 15 to 25 miles from London; whereas in Paris the well of Grenelle is 1,798 feet deep, and derives its supplies from the rain-water falling in the Lower Greensands of Champagne, and travelling above 100 miles underground before reaching Paris. The well of Passy, sunk also through the Chalk into the Lower Greensands at a depth of 1,923 feet, derives its supplies from the same source. The level of the ground above the sea at the outcrop of the Lower Greensands in Champagne averages about 350 feet, and the water at Grenelle well rises 120 above the surface, which is nearly the level of the Seine, there 89 feet above the sea-level. The water-delivery is large and well maintained. These results were considered so encouraging, that in 1865 the Municipality of Paris decided on sinking two Artesian wells of unexampled magnitude. Hitherto the bore-holes of such wells have been measured by inches, varying from 14 to 4 inches, that of Passy alone having been 4 feet at the surface and 2 feet 4 inches at bottom. But it was resolved to exceed even the larger dimensions of this well.

One of these experimental wells is in the north of Paris, at La Chapelle, St. Denis, 157 feet above the sea-level. A shaft, with a diameter of 6½ feet, was first sunk through Tertiary strata to a depth of 113 feet. At this point the boring was commenced with a diameter of 5½ feet, and carried through difficult Tertiary strata to a depth of 450 feet, when the Chalk was reached. A fresh bore-hole was here commenced in August 1867, which in September 1870 had reached the depth of 1,954 feet. The works were stopped on account of the war until June 1871, when they were resumed, and the bore-hole has now reached the great depth of 2,934 feet, with a diameter still of 4 feet 4½ inches. It is now in the Grey Chalk, and it is calculated that the Lower Greensands will be reached at a depth of about 2,300 feet.

The other Artesian well is at the Buttes-aux-Cailles, on the south-east of Paris, at an elevation of 203 ft. above the sea. The Tertiary strata are there only 205 ft. thick. This well is not quite on so large a scale as the other, and is still, at the depth of 1,640 ft., in the White Chalk.

The discharge from these great wells will probably be equal to that of a small river. At Passy, notwithstanding some defective tubage, and the circumstance that the surface of the ground is there 86 ft. above the Seine, the discharge at the surface is equal to 3½ millions of gallons daily; and it has been above 5 millions, or enough for the supply of a town of 150,000 inhabitants.

The question may arise, and has arisen, why, with a like geological structure, should not like results be obtained at London as at Paris; and, to a certain extent, it has been answered. At Kentish Town an Artesian well was, in 1855, carried through

324 feet of Tertiary strata, 645 ft. of Chalk, 14 ft. of Upper Greensand, and 130 ft. of Gault. Instead of then meeting with the water-bearing Lower Greensands which crop out from beneath the Chalk, both on the north and south of London, unexpected geological conditions were found to prevail, to which we shall have occasion to refer presently; and not only were these Greensands found to be absent, but likewise all the Oolitic and Liasic series. The bore-hole passed at once from the Gault into a series of red and grey sandstones, probably of Palaeozoic age, and not water-bearing. The Chalk has more recently been traversed at Crossness, near Plumstead, where its base was reached at a depth of 785 ft., and the bore-hole carried 159 ft. deeper into, but not through, the Gault, when, owing to difficulties caused by the small size of the bore-hole, the work had to be abandoned. Although we were mistaken in our anticipations as to the results of the first of these works, still it is evident—as the Lower Greensands, with a thickness of 450 ft., pass beneath the Chalk and the Gault in a line from Farnham, Reigate, to and beyond Sevenoaks—and they again occupy the same position north of London, on a line from Leighton Buzzard to Potton—that it is only a question of how far they may be prolonged underground towards London. They have as yet been followed only 4 miles from their outcrop under the Gault in Buckinghamshire, and 1 mile in Kent; and no attempt has been made to follow them under the Chalk. It is therefore quite possible that they may extend to under Croydon, or even to Sydenham, or still nearer London; but this depends upon the width of the underground ridge of Palaeozoic rocks, which has not been determined. It is a matter for trial. As the sands are from 200 to 500 ft. thick, and show no sign of an immediate approach to the old shore-line, there is every probability that in Kent and Surrey they extend at all events some miles northward, and in Bucks some miles southward, before they thin off against the underground ridge of old rocks, so that they might still be found available, as a supplementary source, for the water-supply of London.

Such is the geological structure of the ground on which this large city is dependent for its first and immediate water-supply by means of wells. The highest seam of water, that in the drift-gravel, extends almost everywhere under the streets and houses of London, at depths of from 12 ft. to 25 ft., forming what is called ground-springs. The Lower Tertiary sands, with their greater thickness, and their larger and distant area of outcrop, contain the second and larger underground body of water beneath London. The third underground reservoir is the Chalk, which, from its large dimensions—500 ft. to 1,000 ft. thick—and extensive superficial area, forms a still larger reservoir, and source of water-supply.

With the increase of population, however, the need for larger quantities necessitated the recourse to river-supply; and this supply, equally with the other, is regulated by geological conditions, only that in this case the question concerns those conditions which affect the strata throughout the catchment-basin of the river itself above the town which needs its supply.

(To be continued.)

PROF. SCHIAPARELLI'S RESEARCHES

THE following address was delivered by the president of the Royal Astronomical Society, Mr. William Lassell, February 9, 1872, on presenting the Gold Medal of the Society to Signor Schiaparelli:—

You will have learned from the Report just read, that your Council have awarded the Gold Medal this year to Signor Schiaparelli; and I regret to have to inform you that we shall be deprived of the pleasure of presenting it to him in person; as by a letter received from him a few days ago, I learn that his duties of Professor and Director of the Observatory at Milan will prevent his being able to undertake so long a journey.

The first notice I find of Signor Schiaparelli's labours is his discovery of the minor planet *Hesperia*, at the Observatory of Milan, on April 29, 1861, an indication that, besides his mathematical attainments in Theoretical Astronomy, he possesses industry and practical skill as an observer.

In the *Astronomische Nachrichten* of August 13, 1864 (No. 1487), is a purely mathematical paper by him, entitled "Théorèmes sur le mouvement de plusieurs corps qui s'attirent mutuellement dans l'espace." Of this paper, not bearing immediately upon those labours of Signor Schiaparelli which have more especially called forth the award, I will only express the opinion of a friend of high mathematical attainments, who

characterises it "as an elegant and probably original contribution to the theory of the orbits of bodies moving freely in space, and acted on only by their mutual attractions."

I come now to give some account of Signor Schiaparelli's principal discovery of the law of identity of meteors and comets, and of the observations and reflections which led him to that result, as contained in a series of letters to Father Secchi in the year 1866.

It appears from these that Signor Schiaparelli's study of this subject received a great impulse from his own observation of the meteors which fell on the nights of the 9th, 10th and 11th of August, 1866. He states that he was then confirmed in the opinion expressed three years before, that, of the meteors which usually fall on those nights, a great number are distinguished by their starting nearly all from one point. And, from the spasmodic fall of these meteors—more sometimes falling in one minute than in the next quarter of an hour—he inferred that their distribution in space must be very unequal. He also observed that those stars proceeding from one point were all of a fine yellow colour, and left behind them a fugitive but very sensible track; whilst the other meteors, proceeding from various points, offered every variety of colour and form. Hence he concludes that the meteors form a number of rings, and become visible when the earth traverses their orbit, as if shooting forth from one point in the sky. And he remarks that the observations of M. Coulvier-Gravier, and Professor Heis, and of our own countrymen, Professor Herschel and Mr. Greg, have shown that these radial points occur in every quarter of the heavens; therefore these rings or orbits must possess every possible degree of inclination to the ecliptic.

He then proceeds to inquire how such a mass of cosmical matter could become accumulated in the Solar System. This system seems to consist of two classes—the planets, characterised by but little eccentricity of orbit, slight variation of the plane of the orbit, exclusion of retrograde motion, and a tendency to take the form of a sphere (deviating from it only so much as is necessary to preserve the equilibrium of the body)—these characteristics applying also to the secondary systems, with the exception of the satellites of *Uranus*. The second class consists of cometary bodies, which are under no law as to the planes of their orbits, or the direction of their motions. The point most remarkable about them is the extreme elongation of their orbits, most of which are described in stellar space; which seems to show that they did not form part of our system when that was first constituted, but are wandering nebulae picked up by our sun.

Signor Schiaparelli further observes that the velocity of the solar system through space has been shown by Otto Struve and Airy to be somewhat similar to that of the planets round the sun. Now if a nebulous body or comet in motion were to come within the action of the sun, it would go round the sun at such an immense distance from us, that it would remain invisible. Two circumstances might bring it within our range of vision—first, if the comet met the sun in almost a direct line; and secondly, if it were travelling in a direction parallel to the sun's motion.

If we suppose a cloud of cosmical matter formed of particles so minute and so widely separated as to possess scarcely any mutual attraction, to be brought within the power of the sun's influence, each particle would pursue an elliptic orbit of its own. Those particles which differed most in the planes of their orbits would however possess nodes in common, and, in consequence, the particles as they approached the sun would necessarily approach each other, and when separating again, after passing the node, would at their perihelion passage be still very much nearer than they were when brought first within the sun's attraction. Those particles which, lying in the same plane, presented a wide angle with respect to the sun, would form *ellipses*, the planes of which would be identical; though the positions of the major axes would diverge, and, as a result, the particles at their perihelion would pass in nearly the same orbit, but at different velocities, the originally foremost particle being overtaken by those behind it. Again, those particles which, being in the same plane, were also in the same line with regard to the sun—their separation consisting in the variation of their distance from the sun—would form *ellipses* in the same plane, and having a major axis in the same direction, but of different lengths,—the orbit of the particle nearest the sun being described within that of the farthest particle, the result of which would be a difference of speed, and an ever-widening distribution of the particles along the whole of the orbit. This

reasoning is illustrated, in the second letter to Father Secchi, by a series of diagrams and figures; and then Signor Schiaparelli proceeds to give a recapitulation or summary of his principal propositions thus:—Celestial matter may be divided into the following classes, 1st, fixed stars; 2nd, agglomerations of small stars (resolvable nebulae); 3rd, smaller bodies invisible except when approaching the sun (comets); 4th, small particles composing a cosmical cloud. This last class probably occupies a large portion of the celestial spaces, and the motion of these dust-clouds may be similar to that of the fixed stars. When attracted by the sun they are not visible unless they receive an orbit which is an elongated conic section.

Whatever may have been the original form of the cloud, it cannot penetrate far into our system without assuming the form of an elongated cylinder passing gradually into a stream of particles. The number of such streams seems to be very great. The particles are so scattered that their orbits may cross each other without interruption, and may possibly be always changing like the beds of rivers. The stream, after passing its perihelion, will be more diffuse than before; and, when passing a planet, may be so violently affected as to separate or break up, and even some particles may assume quite a new orbit and become independent meteors.

Thus meteors and other celestial phenomena of like nature, which a century ago were regarded as atmospheric phenomena—which La Place and Olbers ventured to think came from the moon, and which were afterwards raised to the dignity of being members of the planetary system—are now proved to belong to the stellar regions, and to be, in truth, falling stars. They have the same relation to comets as the asteroids have to the planets; in both cases their small size is made up by their greater number.

Lastly, we may presume that it is certain that falling stars, meteors, and aerolites, differ in size only and not in composition; therefore we may presume that they are an example of what the universe is composed of. As in them we find no elements foreign to those of the earth, we may infer the similarity of composition of all the universe—a fact already suggested by the revelations of the spectroscopy.

Signor Schiaparelli further pursues the subject in another and later paper, published in No. 1629 of the *Astronomische Nachrichten*, entitled "Sur la Relation qui existe entre les comètes et les étoiles filantes." In this communication he refers to the letters to Father Secchi above referred to, in which he had endeavoured to bring together all the arguments in favour of the opinion of an analogy between the mysterious bodies known as shooting stars and comets.

Signor Schiaparelli, in this paper, proceeds to state that he is prepared to afford to this analogy a large amount of probability, since there is no doubt that certain comets, if not all, furnish the numerous meteors which traverse the celestial spaces. In proof of this Signor Schiaparelli quotes from a paper of Prof. Erman, in which he has pointed out the method of obtaining a complete knowledge of the orbit described by a system of shooting stars, when the apparent position of the point of radiation and the velocity through space of the meteors is known.

Assuming from the necessity of the case that the orbit of the August meteors must be an elongated conic section, Signor Schiaparelli employs the method of Erman to calculate the parabolic orbit of those bodies; taking right ascension 44° and north declination 56° for the position of the point of divergence, according to the observations made in 1863 by Prof. A. S. Herschel. And he proceeds to give the following elements, assuming the maximum of the display of 1866 to be August 10, 18 hours. Comparing these elements of the orbit of the August meteors with those of the orbit of Comet II, 1862, calculated by Dr. Oppolzer, he exhibits the following remarkable coincidence in each element:—

	Elements of the Orbit of the Aug. Meteors.	Elements of the Orbit of Comet II, 1862
Perihelion Passage	23 July, 1862	22 ⁹ Aug., 1862
Longitude of Perihelion	$343^{\circ} 28'$	$344^{\circ} 41'$
Ascending Node	$138^{\circ} 16'$	$137^{\circ} 27'$
Inclination	$6^{\circ} 43'$	$6^{\circ} 25'$
Perihelion Distance	0.9643	0.9626
Revolution Period	105 ⁷ years	153 ⁴ years
Motion	Retrograde	Retrograde

Although the time of revolution of the August meteors is still

doubtful, Signor Schiaparelli, on reference to the catalogues of Biot and Quetelet, deduces a hypothetical period of 105 years, which introduces but small changes in the elements—very inferior to the uncertainty of some of the data on which this determination is built.

In the letters above referred to, Signor Schiaparelli had given an orbit for the meteors of November, assuming the point of radiation as determined in America to be *γ Leonis*. But later observations made with much care in England have shown that this position is erroneous by several degrees, so that that orbit can only be termed a very rough approximation. Assuming, then, that the point of radiation is longitude $143^{\circ} 12'$ and latitude $10^{\circ} 16'$ north—that the maximum of the shower was November 13, 11h. G. M. T.—and that the period of revolution is 33½ years, according to Prof. Newton—Signor Schiaparelli compared the following elements of the meteoric orbit, which he compared with those of the orbit of Comet I, 1866, calculated by Dr. Oppolzer.

Perihelion Passage	Elements of the Orbit of Nov. Meteors. Nov. 10 ^o 02, 1866.	Element of the Orbit of Comet I, 1866. Jan. 11 ^o 160, 1866.
Longitude of Perihelion	$56^{\circ} 25' 9''$	$60^{\circ} 28'$
Ascending Node	$231^{\circ} 28' 2''$	$231^{\circ} 26' 1''$
Inclination	$17^{\circ} 44' 5''$	$17^{\circ} 18' 1''$
Perihelion Distance	0.9873	0.9765
Eccentricity	0.9046	0.9054
Semi-axis Major	10.340	10.324
Revolution Period	33.250 years	33.176 years
Motion	Retrograde	Retrograde.

The assumed position of the point of radiation of the meteors is the mean of 15 determinations obtained by Prof. A. S. Herschel, and given in the *Monthly Notices* of our Society, vol. xvii. p. 19. If this point be advanced 2° in longitude, and 145° be taken in lieu of 143° , the difference of $4'$ in the place of the longitude of perihelion in the above elements will disappear.

Signor Schiaparelli then concludes his memoir in these remarkable words:—"These approximations need no comment—must we regard these falling stars as swarms of small comets, or rather as the product of the dissolution of so many great comets? I dare make no reply to such a question."

In venturing to offer a word or two of comment on this very imperfect résumé of the labours of Signor Schiaparelli, it appears to me that we can scarcely speak of them too highly, or overrate their importance. Granting that his hypotheses are correct,—of which indeed there seems to be a very high probability, some of the most difficult questions in the contemplation of the constitution of the universe seem at once, and as it were *per saltum*, to be solved. To have placed before our view so clear a history of those mysterious bodies—nebulae, comets, and aerolites, and their several and intimate relations pointed out—is an advancement of Astronomical Science I at least individually had not ventured to anticipate. And a collateral advantage resulting from this splendid discovery, is the encouragement given to the careful and diligent observation of phenomena, even when the prospect of a fruitful result is by no means apparent. Had it not been for the patient, systematic, and intelligent observations of Prof. Heis, M. Couvlier-Gravier, Mr. Greg, and Prof. Herschel, Signor Schiaparelli would have wanted many valuable data required in his investigations.

I may finally remark that an important confirmation of Signor Schiaparelli's conclusions appears in a valuable paper of Prof. Adams, in our *Monthly Notices*, vol. xvii. p. 247, in which from somewhat different data, including some observations of his own, he calculates elliptic elements of the November meteors generally very accordant with those above given.

SOCIETIES AND ACADEMIES

LONDON

Geological Society, March 6.—Prof. Duncan, F.R.S., vice-president, in the chair.—(1.) "*Prognathodus Guntheri* (Egerton), a new genus of fossil Fish from the Lias of Lyme Regis." By Sir P. de M. Grey-Egerton, Bart, M.P., F.R.S. In this paper the author described a new form of fossil fish, having a broad premaxillary plate somewhat resembling the incisor tooth of a gigantic Rodent, a single auxiliary plate like that of *Callorhynchus*, and a mandibular dental apparatus closely resembling that of *Cochliodus*. For this form he proposed the establishment of the new genus *Prognathodus*, and named the species *P. Guntheri*. *Ischyodus Johnsoni*, Agassiz,

also probably belongs to this genus, as it agrees with *P. Guntheri* in the characters of the premaxillary teeth. The author was doubtful as to the exact position of this genus, which had a head extended in a horizontal instead of a vertical plane, suggesting a resemblance to *Zygana*, but covered with hard plates like the head of a sturgeon, and exhibited in the dental apparatus the curious combination indicated above.—Dr. Gunther pointed out the interest attaching to the denition of this fossil fish as proving the connection between the Ganoid and Chimaeroid forms. The existence of three teeth instead of one on each side of the jaw, as in *Ceratodus* and others, presented in it a generic character; but the type was still the same. Mr. Etheridge made some observations as to the horizon in the Lias in which these fossil fishes occurred. He believed that nine out of ten of the Lower Lias Species came out of the upper part of the *Bucklandi* limestone series. Sir P. Egerton corroborated Mr. Etheridge's views as to the localisation of species of fish, and agreed with him as to the importance of recording the exact position of all such fossils.—(2.) "On two specimens of *Ischyodus*, from the Lias of Lyme Regis." By Sir P. de M. Grey-Egerton, Bart, M.P., F.R.S. In this paper the author noticed a new example of the greatly developed rostrum of a male Chimaeroid, an inch shorter, more slender, and more attenuated at the apex, than that of *Ischyodus orthorhinus* Egerton, having a projecting median rib along the upper surface, and the tubercles of the lower part smaller and fewer than in *I. orthorhinus*. For this form the author proposed the name of *I. leptorhinus*. Also a dorsal fin-spine, with the cartilages to which it was articulated, showing the mechanism of its attachment very clearly. This spine differs from that of *I. orthorhinus* in being straighter and smoother, and having fewer and smaller tubercles. The author regarded it as probably belonging to *I. leptorhinus*.—(3.) "How the Parallel Roads of Glen Roy were formed." By Prof. James Nicol, F.G.S. In this paper the author endeavoured to explain, in accordance with the marine theory of the origin of the Parallel Roads of Glen Roy, the coincidence of the level of these terraces with that of the different cols, and also how the same sea could have produced terraces at different levels in different valleys. He assumed that during the gradual elevation of the land, the gradual closing of the straits between its separate masses by the elevation of the cols above the surface would, by checking the eastward flow of the tidal current, cause the sea-level in the western bays to remain stationary relatively to the rising land; and during this period the marine erosion would take place along a line corresponding in level to the col. Hence, in Glen Gloy, which has only one col, the highest in the system, the highest road only was formed; and Glen Gloy remained unaffected by the stoppage of those cols which produced three roads at lower levels in Glen Roy, the lowest of them also extending round Glen Spean. Professor Ramsay entered into the history of the theories for accounting for the terraces, the first of which, that of Professor Agassiz (in 1840), accounted for them by a great glacier damming up the valley, and from time to time declining in height. The glacial theory, on which this view rested, had to some extent been doubted, but eventually had been almost universally accepted even by its first opponents. He next cited the works of the late Mr. Robert Chambers as to the existence of old sea-margins, pointing to a gradual sinking of the sea or a rising of the land. There could be little doubt that a great part of Scotland and of the northern part of England, had been at one time covered with glaciers, as had also been the case in other parts of Europe. Unless the whole country had been submerged, and then came up again by a succession of jerks, it seemed impossible that such terraces could have been formed by the sea and still have remained in existence. If, however, there had been great oscillations in temperature, it seemed possible that during the decline of some transverse glacier the varying levels of the lake might have left terraces, traces of which might still be preserved. Mr. Gwyn Jeffreys renewed his protest against regarding these beds as marine unless marine remains were found in them. In Prof. Nicol's former paper, mention, however, had been made of rolled boulders. These occurred at Glasgow, and elsewhere, covered with *Bolani*. As, however, no marine remains had been found in Glen Roy, he adopted the freshwater theory. Mr. Evans regretted that no one else was present who would in any degree advocate the author's views. He pointed out that if the surface of the rocks below the detritus in Glen Roy was glaciated, the probability was in favour of the superficial drift being of marine rather than of subaërial origin. He much doubted

whether Ben Nevis, or any of the mountains of the district, offered a sufficient gathering-ground for any such glacier as that supposed in the freshwater theory, assuming the climate to have been such as would have admitted of a large lake in Glen Roy. He suggested the possibility of the openings through which the sea would gain access to the district having at the time of the last submergence been to some extent choked with ice, which thus checked the tidal action inland from the present coast; and thought that possibly both glaciers and the sea had together contributed towards the formation of the terraces. These, he observed, were by no means confined to Glen Roy itself, but were to be seen on a large scale, and at a lower level in the valley of the Spean, if not elsewhere.

PARIS

Academy of Sciences, March 11.—The following mathematical papers were read:—On flattened curves, by Mr. A. Cayley, communicated by M. Chasles; on the determination of the characteristics of the elementary system of cubics, by M. H. G. Zeuthen, also presented by M. Chasles; and on a change of variables, which renders certain equations with partial derivations of the second order integrable, by M. J. Boussinesq, presented by M. de Saint-Venant. M. de Saint-Venant also presented the continuation of his memoir on the hydrodynamics of water-courses.—Papers on auroras were communicated by Marshal Vaillant, M. Vinson, M. H. de Parville, and M. H. Tarry. M. Vinson's communication, and two extracts from letters read by Marshal Vaillant, related to a magnificent Aurora Australis observed at the Island of Bourbon (Réunion) on the night of February 4-5.—M. C. Saint-Claire Deville presented a note by M. A. Houzeau on the chloroform of ozone contained in the air of the country, and on its origin.—M. W. de Fonvielle presented a note in continuation of that read at the previous meeting on the means of protecting habitations against the perils of lightning strokes induced by gas-pipes, &c.—A report, by M. Coumbary, on the prediction of earthquakes, was read.—M. E. Becquerel presented a note by M. A. Cazin on the quantity of magnetism of electro-magnets.—M. Delaunay communicated a paper by M. A. M. Mayer describing some experiments, showing that the translation of a vibrating body gives origin to a wave of different length from that produced by the same vibrating body in a fixed position.—A note by M. H. Resal on the geometrical theory of the movement of the planets was also presented by M. Delaunay.—A paper was read by M. Kolb on the densities of hydrochloric acid; it contained some useful tables.—M. Blanchard presented a note by MM. P. Fischer and L. de Folin on their dredgings in the fosse of Cap Breton during the year 1871. These dredgings were made at depths extending from 24 to 250 fathoms. The authors indicate the principal species of animals obtained by them.—M. de Quatrefages communicated a paper by M. E. Perrier containing a summary of his anatomical investigation upon the earthworm, and M. Coste a note by M. G. Pouchet on changes of colour produced in prawns to accommodate them to the colour of surrounding objects. This change of colour is prevented by removing the eyes of the prawns.—M. A. Leymerie described some geological peculiarities in the lower Pyrenees.

March 18.—M. Serret presented some remarks on the note by Mr. Boussinesq, read at the last meeting of the Academy, and stated that M. Boussinesq was long since anticipated by Lacroix in the transformation proposed by him.—M. Serret also presented some remarks by M. E. Combesure, upon an analytical memoir by Legendre, on the integration of certain equations with partial differences.—M. de Saint-Venant read a continuation of his memoir on the hydrodynamics of water-courses.—M. H. Saint-Claire Deville communicated a note by M. D. Gernez, on the absorption spectra of the vapours of sulphur, selenious acid, and hypochlorous acid. The author finds that coloured vapours in general absorb rays of irregularly variable refrangibility. Vapour of sulphur at first produces a gradual extinction of the spectrum, except the red part a little beyond line C of the of the solar spectrum; with an increase of temperature the rest of the spectrum reappears with very distinct bundles of lines in the violet and blue, and returning into the green. Vapour of selenious acids produces a very distinct system of absorption-bands in the violet and blue, and the absorption-spectrum of hypochlorous acid is identical with that of hypochloric and chlorous acids.—M. H. Tarry presented a note on the extraordinary extension of the zodiacal light, and its coincidence with the periodical reappearance

of auroras; and the aurora of the 4th of February was the subject of notes by MM. Denza, Mohr, and Coumbary.—M. Tarry and M. Denza also noticed the sand rains of the South of Europe.—M. C. Saint-Claire Deville also presented some remarks on a note on the theory of auroras, read at the last meeting by Marshal Vaillant.—The papers on chemical subjects were particularly numerous. M. Chevreul read a memoir on a phenomenon in the crystallisation of a very concentrated saline solution.—A paper on the formation of chloral by MM. A. Wurtz and G. Vogt was read.—The question of the preservation of wine by the application of heat was further discussed by MM. de Vergnet-Lamotte and Pasteur.—M. Wurtz presented a note by MM. C. Friedel and R. D. Silva, on the isomers of trichlorohydrine and the reproduction of glycerine; a note by M. G. Bouchardat on the transformation of acetone into hydride of hexylene (dipropyle); and some facts with regard to diphenylamine by MM. C. Girard and G. de Laire.—M. C. Robin presented some observations by M. E. Ritter, on colourless bile, in which the author stated that in all cases where colourless bile occurred the liver presented more or less fatty degeneration.—A note was read by M. Duclaux on the influence of the cold of winter upon the seeds of plants.—M. Decaisne presented a note by M. E. Bornet, on the gonidia of Lichens, in which the author supports the curious opinion put forward by M. Schwendener, that the lichens are complex organisms, formed by the association of certain low algae with fungi or other plants. He regards the connection as one of parasitism.—A note was read by M. S. Meunier on the discovery of an abundant deposit of *Hemirhynchus Deshayesi* in the Calcaire Grossier of Puteaux.—M. C. Bernard presented a note by M. Ollier, on cutaneous grafts, and a note by M. Guilbert on the beneficial results obtained by the combined action of morphine and chloroform in surgery.

THE FOUNDATION OF ZOOLOGICAL STATIONS

II.—THE AQUARIUM AT NAPLES

WHEN I wrote the first article on the "The Foundation of Zoological Stations,"* I desired to bring before the general public the idea of extending the principle of co-operation in Science in general, and in Biology in particular. I now propose to give a sketch of the internal organisation of a zoological station as it presents itself to my mind. It is natural that in doing this I give more or less a picture of what I intend to produce at the station which is at present being erected under my superintendence at Naples.

The building occupies an area of 7,000 square feet, and is situated at a very short distance—100ft.—from the sea. It forms a rectangle 100ft. long and 70ft. broad, with a height of 40ft. The building is divided into two parts, the lower part being occupied by the tanks of the great aquarium, which is to be open to the public; the upper part containing twenty-four rooms of different sizes for laboratories, a library, and collections, and for lodging the three or four zoologists who will be constantly occupied in managing the station.

I will not speak here of the manner in which the technical parts of the aquarium are to be arranged, as this would scarcely interest my readers. What I should like to specialise a little relates more to the facilities for scientific study which the station will afford.

Let me speak first of the lower part of the building, the great public aquarium. It will contain fifty-three tanks of different sizes, one of them 3ft. long, 10ft. broad, and 3ft. to 6ft. deep; twenty-six 6ft. 6in. long, and equally broad; and twenty-six others 3ft. long and 3ft. to 6ft. broad. These tanks will contain marine animals of all kinds, either isolated or more or less mixed, according to the investigations that are to be made.

I imagine now that in one of these tanks a number of *Medusæ* and *Salpæ* are together, and the problem is to know how they will behave in so close a union. This can be solved only in such a tank, and it will be a very easy study, as the naturalist has only to occupy a movable chair, which is placed before the tank, and which hides him and the tank by special precautions completely from the general public. At a certain moment you can put into the tank some rapacious fishes, or some of the swift and warlike Crustaceans of the *Palæmon* tribe, and wait for the movements and actions of the *Medusæ* as well as the *Salpæ*. You may repeat these observations, and add other different species; and if you have patience enough, you cannot fail to discover facts about the general habits of the animals in question, and the functions of their organs, which were unknown before, and which may yield, perhaps, valuable arguments to establish a theory on the manner in which they originated from other animals. As it is, we hardly know anything about the life of *Medusæ* or *Salpæ*, and our ignorance of the habits of other marine animals is equally great.

* NATURE, vol. v. p. 277.

Let us take another example. I was present when half a dozen stone crabs (*Lithodes Maya*) were brought from Norway to the Hamburg Aquarium. Mr. Lloyd, at that time the Director of the Aquarium, distributed them in several tanks. It happened that one of them found itself in company with a number of *Cerilabrus norwegicus*, a swift and clever little fish. These at once began to attack their new companion. With considerable skill they tried to hurt the eyes of the crab, which on their long stalks presented, of course, the most vulnerable part of the clumsy and spinous animal. After half an hour's continued attacks the fishes actually succeeded in tearing out one of the eyes. This fact made me investigate at once the mode of protection with which Nature had furnished the eyes of Crustacea, and I collected a considerable number of observations, which, if completed and worked out, would possibly form a very interesting chapter in our knowledge of the progress of Natural Selection.

I shall adduce a third instance for the necessity of facilitating observations of this kind. In his excellent refutation of some of Mr. Mivart's objections to the theory of Natural Selection, Mr. Darwin relates ("Origin of Species," 6th Edition, p. 186) some observations made by Malm on the way in which the eyes of the *Pleuronectes* get both on one side of fish. The following are his words:—

"The *Pleuronectidæ*, whilst very young and still symmetrical, with their eyes standing on opposite sides of the head, cannot long retain a vertical position, owing to the excessive depth of their bodies, the small size of their lateral fins, and to their being destitute of a swim-bladder. Hence, soon growing tired, they fall to the bottom on one side. Whilst thus at rest they often twist, as Malm observed, the lower eye upwards, to see above them; and they do this so vigorously that the eye is pressed hard against the upper part of the orbit. The forehead between the eyes consequently becomes, as could be plainly seen, temporarily contracted in breadth. On one occasion Malm saw a young fish raise and depress the lower eye through an angular distance of about seventy degrees. We should remember that the skull at this early age is cartilaginous and flexible, so that it readily yields to muscular action. Besides, Malm states that the newly-hatched young of perches, salmon, and several other symmetrical fishes, have the habit of occasionally resting on one side at the bottom; and he has observed that they often then strain their lower eyes so as to look upwards; and their skulls are thus rendered rather crooked. These fishes, however, are soon able to hold themselves in a vertical position, and no permanent effect is thus produced. With the *Pleuronectidæ*, on the other hand, the older they grow the more habitually they rest on one side, owing to the increasing flatness of their bodies, and a permanent effect is thus produced on the form of the head and on the position of the eyes."

I think observations of this kind ought to speak so much in favour of a great observatory for marine animals, that it would be superfluous to add any more instances for its necessity. I hope the Naples Institution will rapidly produce a great number of similar observations, and thus render one of the most important services to the still utterly neglected knowledge of the animal life of the ocean.

Let us now ascend the staircase from the lower part of the future Zoological Station to the upper floor. We pass through a series of rooms on the north side, the first of

which is occupied by the chief zoologist. Before the window a table for microscopical work is placed, surrounded by small tanks for breeding eggs and keeping alive larvæ and other smaller animals. Each tank is furnished with a continuous current of fresh sea-water, which can be weakened or strengthened, or completely stopped, as it pleases the zoologist. The rest of the room is reserved for the business matters of the station. Next to it comes the library-room, large enough to keep a library of 25,000 volumes. Two tables for microscopical work placed near one another occupy the place near the window, some tanks of different sizes, completely furnished with tubes, &c., are placed at the disposal of those who occupy the tables. Next follows the great laboratory. In the centre of the room we find at least twenty to thirty tanks of different sizes, each of them with its own current of sea-water; the two great front windows afford light for four working tables placed near them. The walls may be occupied by physiological instruments and by other apparatus which will be required. Galleries on the walls and across the centre of the room yield enough space for placing all sorts of collections and other things on them without hindering the free passage in the laboratory. The last room on this northern side will be occupied by the first assistant zoologist, and be furnished, like that of the chief zoologist, with working table and tanks. Both the corners of the house are occupied by towers, and these towers contain two small chambers of nine feet square; they are also to be furnished with tables and some tanks, so that in all ten zoologists may, at the same time, find complete accommodation for their work.

The south side of the upper part of the station will be occupied by four rooms, sufficiently large to allow the collections to increase for many years, and the laboratory to take possession of double the space it will occupy at the beginning. The west and east side afford some private rooms for the use of the naturalists employed in the management of the station. Under the roof eight other smaller rooms complete the whole disposition of the space inside the building.

Now let me say some words on the functions these organs of the Zoological Station are to exhibit in future. There are first to be noticed the great advantages which will be offered to the single student. Whoever works with marine animals will be painfully acquainted with the difficulty of preserving them alive longer than two or four days. They almost invariably die, and decompose very soon. If one now considers that anatomical and still more embryological problems are only to be solved during weeks or months of undisturbed and indefatigable exertion, it is quite evident what enormous advantage must result from the possibility of keeping these animals alive during weeks. And this will be effected by the help of tanks with a continuous stream of sea-water. The sea being always in motion, caused either by the waves or still more by the vast number of currents, makes the constant alternation of fresh and aerated sea-water necessary for the life of the animals. The imitation of these currents and the artificial injection of air into the tanks will render it possible to keep even embryos and larvæ alive, which

formerly could never be studied on account of their early death.

Besides, everybody knows how often fishermen bring eggs or larvæ which are completely unknown to the zoologist. They are, perhaps, highly interesting; perhaps belonging to animals whose eggs have never been seen before, as they deposit them far off in the open sea or on the bottom. The single zoologist in his small room in a Naples Hotel, with some bottles or basins at his disposal, puts them into a tumbler, changes the water regularly, and thus succeeds in keeping them alive for a week, but he forgets the changing once, and to-morrow they are dead. A good many will even not live in spite of the changing of the water, because they require the constant stream running over them. The single zoologist in the station, on the other hand, puts them into a tank, sets the stream in motion, and has nothing to do but to watch their development, and the final disclosure of the embryo, or the metamorphoses of the larvæ, and may completely succeed in getting a key to their nature and their relation to other animals.

Considering now the all-importance of embryology and development in the present state of zoology, it is easy to recognise in the continuous stream of the sea-water in the station a fundamental novelty in the conditions for the progress of scientific zoology. Go a little further. It is rarely advisable to work with one subject alone when on the sea-coast. There are so many incidents that change the conditions of the work you have in hand, that you are much wiser to have, whilst working at one chief problem, one or two smaller ones with it. But chance is often a paradoxical thing; it will entirely inundate you one day with excellent material for all these problems, and cause you great embarrassment as to what to take first; and another day it will yield you nothing whatever, so as to force you to idleness. Now again with a series of tanks and streaming sea-water you can pursue everything quite at your leisure, stop one investigation when you like, or take up another, or drop them both, and work for one day with some interesting novelty, without being afraid of spoiling the material of the old objects, and losing the opportunity of getting through it. And everybody knows what a consolation it is to be always capable of taking your principal line of work up again, whilst you are not forced to deny yourself the chance of taking some notice of new arrivals, if it even were only for a little instructive side glance of some hours.

These are some illustrations of the great facilities and advantages of the station, yielding thus in future to scientific workers immense economy of time, money, and power. But this is not all that the station will do. Every well-instructed biologist is aware of the great step anatomical science made when first Cuvier created and afterwards Johannes Müller reformed Comparative Anatomy. The description of the different types, the organs and their homologies, their histological constitution, similarity and dissimilarity, became well worked out, and extended the range of our insight over almost all living animals.

Physiology ought to have gone the same length, following exactly the lines of anatomical research, to tell us something about the functions of all the organs and

structures through the whole range of animal life. But physiology did not do so; it got into another line, investigating with the utmost care, and also with splendid success, the nervous functions of the higher vertebrates, developing theories on the physical agency of these functions, and trying to verify these theories by experiments. It went also into chemical researches, trying to get clear insight into the chemical processes of digestion and the nourishment of the body of the higher vertebrates. In consequence of this one- or rather two-sidedness, it has happened that physiology appears to be very indifferent to the great overthrow of our views regarding the organic world, caused by the doctrine of evolution. Indeed, celebrated physiologists even go so far as to deny the truth of that doctrine altogether. Now nothing can be a stronger proof that there is something amiss in the state of physiology, and this something consists in the complete want of Comparative Physiology. If we cannot understand the anatomical constitution of men and the higher animals without the study of comparative anatomy and embryology, we can equally as little understand their physiological components if we do not follow them up through the whole series of animal life. It is utterly deplorable that so very little has been done in this immense department of Science. What do we know of the functions of such all-important organs as the so-called segmental organs of Annelids, which in the further development of other classes of the animal kingdom grew into some possessing the highest functions? Nobody doubts that Amphioxus is a Vertebrate; but has any one yet tried to make physiological experiments with that animal, though it is one of the most hard-living of all marine animals? And is there in any way a base laid for the physiology of fishes, which must yield results of the utmost importance? Does the academical physiology of modern times do the least to unveil the mysteries of generation, of growth, of degeneration? Are these departments, perhaps, less interesting, less important, less accessible than Nervous Physiology or the Physiology of Digestion? There is apparently a lack of idea in this great department of Biology, an overgrowing influence of Physicists, and a want of morphological knowledge among Physiologists. What would have been the fate of Physiology if, unfortunately, Johannes Müller had not died in the same year when the "Origin of Species" came out? He was the man to create at once the study of Comparative Physiology, and his spirit must again come over physiologists to enable them to perceive the immense field of action before them, and the neglect with which they treat it.

Now, I can only say that it is one of the great objects of the Naples station to do all in its power to carry on a fair commencement of Comparative Physiology. Whatever money may be spared, whatever pains bestowed, it will willingly be given to so important a duty, and it would be considered a great good fortune should a thoroughly instructed physiologist make up his mind to accept a post in the station in order to establish and carry on a Physiological Laboratory.

To all the possible advantages of the station for the intermittent action of single naturalists alluded to above, unite now the great advantage from the fact that such isolated action will be quite superseded. A station like that of Naples wants at least three well-trained zoologists

to conduct it properly. One of the greatest privileges for these zoologists will certainly be that teaching forms no essential part of their duties. Whoever knows by experience what a loss of energy and of time is caused to all those original workers who are bound to teach daily on elementary topics, what great relief vacations form in the life of university professors and privat-docents (who generally proceed with original work daily during their vacations), will be aware of the exceeding value of paid places where teaching is no necessity, and is only admitted for single and special purposes. The comfortable system of English fellowships, granting money to young gentlemen who are supposed to merit special rewards by having undergone some examinations, will, in fact, be united to the principle of Continental academies, of paying men of scientific reputation, that they may go on at their leisure with original scientific work. The zoologists in the stations will be selected from the number of young professors or privat-docents, who, as a matter of course, are supposed to be ambitious to do some good things in science, even at the risk of sacrificing comfort and agreeable social life. They will be sufficiently paid, and their payment even raised so as to equal that of a moderately-paid German university professor; though perhaps not approaching the level of the payment of a young Oxford or Cambridge Fellow. Nevertheless, they will be put in a position to balance that inferiority by making themselves known as workers, and adding to the storehouse of science facts and observations which may secure to them, if not a comfortable position in life, yet at least applause and respect from the eminent men of their science.

And these zoologists, having at their disposal a laboratory of the perfection and extent of the future Naples one, being aided by the possession of an all but complete biological library, and having before their doors the immense storehouse of the Mediterranean Sea, cannot fail to effect a great step in organising the progress of biological work. Let us suppose the question arose whether Cephalopods preceded in geological time other Molluscs, or were a higher developed offspring of them. The problem would be completely insoluble to University zoologists. But the three zoologists of the station at Naples would at once proceed with a solution in working out the embryology of the seven or eight species occurring in the Gulf, communicating and controlling each other's observations and conclusions. Some foreign zoologists might join their labours for half a year, and Science would be at once in possession of some thoroughly worked out contributions to the Comparative Embryology of the Cephalopods. Apply the same system of co-operation to other problems, for instance to one the solution of which is so much longed for, as the Embryology of Sharks. Years will not enable a single worker to go through that enormous task, with the sole aid of his individual opportunities. But suppose the leading zoologist of the station got the plan into his head to carry out the solution of this problem. He invites some excellent zoologist who completely understands the problem to come to Naples, to bring with him two or three assistants who have already beforehand been made acquainted with the object of the inquiry and the chief difficulties of the observation, and to set to work from

the very first day of their arrival. He himself will do all in his power to procure every day fresh material of all kinds; by the help of the small steam yacht of the station he may succeed in carrying over to the station sharks which were taken two hours before, so as to secure the life of the embryos without any danger of destruction. Then he can isolate and feed them, and make them live as long as he wants. Any one who knows the fauna of the Mediterranean knows also what a large number of different species of rays and sharks arrive in it, and all these could be readily placed at the disposal of the embryologists, thus enabling them to overcome at once immense difficulties which have hitherto been almost completely unassailable.

The station will have several people, fishermen or guards, who by-and-by will be completely acquainted with the fauna of the bay, and will be able to collect whatever is necessary. As very often rare or much-wanted animals come in with some current in great quantities and disappear even the next day, such animals may at once be taken in great numbers and distributed through a great number of tanks, so as to keep them alive for future time.

Very often zoologists from the Universities have just four or six weeks' leisure, and would very much like to do some original work on the shores of the Mediterranean. But to go there for so short a period, to lose so much time in getting up all the necessary arrangements, and spend so much money for so small and uncertain scientific profit, is rather inadvisable for those who have to live on small incomes. But suppose the station is ready, zoologists announce some weeks beforehand their intention to come to Naples, and to work with this or that object, what is easier and what more comfortable than to arrive at the fixed date, to find lodging, laboratory, library, and material all ready and in the very best state, and to go over a ground of scientific work in six weeks, which otherwise would, perhaps, have occupied three months.

And will not the establishment of the Naples Station enable even those to come and work there, who (like many of the very best German and foreign zoologists) do not command means large enough even for a stay of two or three months at their own expense? Will not the constant presence and the collected experience of the station-zoologists save the foreign naturalists all the trouble and annoyance which inevitably result to every one who is not well acquainted with the ways and modes of life and customs of a place so complicated, and in every way so strange, as Naples? And, on the other side, will not the presence of the three station zoologists guarantee Science that it shall not lose the fruits of all that work which was begun but could not be finished by foreign zoologists, since their teaching duties forced them to go home and leave it uncompleted behind? Easily enough one of the station zoologists takes it up and carries it on to a point where it may be fit for publication, thus preserving the labour and energy spent on it.

But I could continue preaching and preaching on a chapter which ought to be clear to every one who understands the progress of Science. I trust that what has been said is sufficient to procure the assistance of all those who think it a pity that whilst millions and

millions are accumulated for the pleasure of individuals who very often do not care a bit for the welfare or the progress of their fellow creatures, schemes like the present, so evidently adapted for throwing open new lines of inquiry into the mystery of the universe, and by that means adding to human progress and happiness, should be abandoned to chance and to isolated individual goodwill and effort.

Naples, March 9

ANTON DOHRN

SCOPE ON VOLCANOS

Volcanos. By G. Poulett Scrope, F.R.S., &c. Second Edition revised and enlarged. With Prefatory Remarks. (London: Longmans, 1872.)

THE subject of volcanos is one which possesses a popular as well as a purely scientific interest, and the more so of late years, since it seldom happens that the foreign mails come in without bringing us tidings of volcanic outbursts or earthquake shocks, often fearfully disastrous, which have occurred in some one or other part of the globe; so that it is but natural to expect that the appearance of a revised and enlarged reissue of the second edition of the well-known work on volcanos by the distinguished and veteran geologist Mr. Poulett Scrope, will attract the attention, not only of geologists, but of the scientifically inclined public in general.

It is not saying too much, when we express our opinion that no geological library can be considered complete without Mr. Poulett Scrope's work; but at the same time it is fairly open to question as to whether this volume in its present form can in 1872 be regarded as an improvement upon what it was before in 1862; since, with the exception of a list of the earthquakes and volcanic eruptions which have occurred since the year 1860, the additional matter, introduced into it as a sort of postscriptum preface, is of a purely discursive and theoretical character, and for various reasons not likely to meet with that general acceptance, from those posted up to date in the subject, which the mass of excellent observational and descriptive matter embodied in the book itself is fully entitled to.

To render full justice to Mr. Poulett Scrope as a vulcanologist, we must, however, carry ourselves back nearly half a century, to the time when the first edition of this work appeared in print; for it is only by so doing that we can be enabled to thoroughly appreciate the importance of his labours in the study of these wonderful phenomena, or to understand how largely they contributed to bring about the substitution of sounder doctrines concerning the formation and structure of volcanos, instead of the very erroneous, yet all but universally received hypotheses, which at that time were taught in the schools of natural science.

If now we proceed to analyse the contents of the volume before us, its perusal will soon show that it devotes itself exclusively to the consideration of the subject treated only from a purely physical and geographical point of view, and as such, it must be admitted to be a most elaborate digest of what is known relating to what may be termed the mechanics of volcanos, their physical structure, and their local distribution over the surface of the

earth; whilst at the same time the very excellent descriptions of the phenomena attendant on volcanic outbursts in their different phases, and the building up of cones and mountain chains, are of the greatest value to the student, and the more so from their being, in many instances, founded upon the personal experiences of the author, whose accuracy as an observer in the field can only be fully appreciated by those who, like the writer of this

notice, have had an opportunity of following in his footsteps, and examining on the spot localities which Mr. Poulett Scrope has so well described in his memoirs.

In the present volume, the illustrations which are so necessary to a work of this character are not only ample, but are in many instances particularly well selected, so as to express exactly what the author intends to convey. As an example, the following woodcuts, Figs. 1 and 2, borrowed

FIG. 1.—VIEW OF STROMBOLI, FROM THE NORTH

from page 31 of the volume, which represent, in elevation and plan, the volcanic Island of Stromboli, or so-called Lighthouse of the Mediterranean, convey to the mind at a glance the main features of a volcanic cone with its crater, of which, as is so common, the one side of the lip has given way. We may also refer especially to two other woodcuts, Figs. 60 and 61, page 232, as an instance of the extremely happy way in which a comparison is made visible to the eye between the principal features of a region of terrestrial volcanic activity, and those of a portion of the visible surface of the moon, in order to point

FIG. 2.—PLAN OF THE ISLAND OF STROMBOLI

out in the words of the author (p. 231) that "the analogy is so close, that it is impossible for a moment to doubt the volcanic character of the lunar enveloping crust."

The perusal of this volume, however, also shows that the mineralogy and petrology of volcanos is but barely touched upon, and that the work in reality treats only of one half of the subject under consideration, giving only the purely physical or mechanical, whilst it leaves out of consideration the other half, or equally important chemical one, in which so much has been done during the last twenty years, and without the due consideration of which, it

is self-evident that no confidence can or ought to be placed in conclusions drawn as to the causes, probable seat of, or many other questions relating to volcanic action, or to the nature of the interior of the earth itself, which is so intimately connected therewith; and it is on this account that we have purposely abstained in the present notice from criticising the theoretical views and deductions of the author.

In conclusion, whilst we, for the reasons before mentioned, heartily recommend Mr. Poulett Scrope's "Volcanos" to the mature consideration of every English student in this branch of geology, we at the same time advise that it should be studied in connection with the admirable memoirs of Bunsen, v. Waltershausen, and others, which have of late years thrown so much light upon the nature of volcanic phenomena, in order that by making himself conversant with the two great forces in Nature, physical and chemical, he may be the better enabled to arrive at sound conclusions.

DAVID FORBES

OUR BOOK SHELF

Quarterly Weather Report of the Meteorological Office.
Part III. July to September 1870. (Stanford, 1872.)

THIS, the new number of the *Quarterly Weather Report*, is in point of care the equal, in some minor details of execution the superior, of all former numbers. The method of showing the wind's velocity by a shaded curve, which has been adopted since the first part of this series, adds much to the ease with which the graphic representation can be read, and is a decided improvement; so is the introduction into the margin of the miniature charts of barometric pressure during strong winds. The engraving too is clearer and finer than in some of the past numbers, and is perhaps as nearly perfect as can be. After a few years the accumulated numbers of these reports will form a most valuable record. There are many students of

meteorology still impressed with the idea that, with a correct knowledge of what has been, we may be able to form an opinion of what is to be. It seems to us by no means improbable that with more accurate information, such as this now being stored for future use, we may before long arrive at the power of foretelling the general character of seasons, in regard to their being wet or dry, hot or cold, stormy or gentle; but we see no reason to believe that any amount of study of the past will ever enable us to predict in detail for any length of time in advance, though it may and must lead us to a better capability of rightly interpreting the atmospheric changes going on, of detecting them at their earliest beginning, of judging their probable effects, and thus of extending the period for which "storm warnings" may be made available. With increased experience new power will be gained, new methods will be learned and proved. Even now, the spectroscopic observations by Commander Maclear, to which he called our attention in these columns only a few weeks ago, seem to point hopefully towards a new path in meteorological research; for it is not only in the widely different climate of the Bay of Biscay, the Red Sea, and the Indian Ocean, that he observes the differences in the spectrum which he has spoken of in the article just referred to; he informs us that his later observations lead him to believe that the changes in the atmospheric humidity distinctly correspond to changes in the solar spectrum; that, for instance, an increasing humidity manifests itself by a shortening in of the blue, and by a well marked development of aqueous bands in the red and yellow. Whether further examination will confirm this belief or not it is at present impossible to say, but the spectroscope has done so much towards teaching us the constitution of other atmospheres, that we may fairly entertain a hope that the time has come for it to teach us something about the distant and outlying parts of our own.

J. K. L.

Index of Spectra. By W. M. Watts, D.Sc. (London: Henry Gillman.)

ALL workers with the spectroscope must have felt the great inconvenience arising from the employment of numberless different scales in the mapping of spectra. It is to be hoped that at some future time there will be more uniformity, and that authors, when publishing original memoirs, will reduce their measurements to a definite and recognised system. It is clear that such a method must be perfectly independent of the spectroscope and its concomitant parts; the position of each line can therefore only be expressed by its colour, or, in other words, by the length of the wave of light which produces this colour. Dispersion spectra, obtained by the use of prisms of different materials, vary greatly in the relative breadth of the respective colours; thus in the spectrum from crown-glass the red end is larger and the blue end shorter than in the spectra obtained from flint-glass, carbonic disulphide, and by diffraction. It is therefore necessary in spectroscopic researches to record the positions of numerous well-known lines as observed in the instrument that is used. In a diffraction spectrum, however, the position of the lines is dependent solely on their colour, and is precisely the same by whatever method the spectrum is obtained. For the results of different observers to be accurately comparable, the readings obtained by dispersion must either be expressed in wave-lengths, or the spectra must be obtained by diffraction. The wave-lengths of the Fraunhofer lines of the sun have been accurately determined by several observers. The author has adopted as the basis of his work the measurements made by Angström, as these appear to exceed in accuracy all similar measurements at our disposal. When the wave-lengths of a number of lines are known, it is easy to calculate the wave-lengths of the lines of any new spectrum, either by the interpolation formula given by W. Gibbs *Phil. Mag.* [4] xl.157) or by the method of graphical inter-

polation, both of which methods are explained in the volume before us; all that is required is to have the wave-lengths of two known lines, between which the line to be measured falls. By the aid of Angström's measurements the author has reduced the measurements of the bright lines of all the elements whose spectra have been carefully investigated, and also of air lines as mapped by Thaler, Huggins, and Plucker. These tables will therefore assist materially in the work of reduction, by serving as landmarks from which to calculate the wave-lengths of new lines. The attention that the author has bestowed on this work is the best guarantee of the accuracy of the numbers given. In the lithographic plates at the end of the tables, a drawing of the spectrum of each element is given on the plan proposed by Bunsen, in which the intensity of a bright line is indicated by the height of the line representing it; a chromo-lithograph is given of the double spectra of nitrogen, sulphur, and carbon, and another plate, showing two spectra obtained by Wülfner from aluminium, and three from hydrogen at different powers. Dr. Watts is deserving of the best thanks of all those interested in spectroscopic work, for it is to be hoped that his "Index of Spectra" may contribute to the adoption of a uniform scale of measurement, and thus facilitate the advance of the science. LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

The Adamites

PHILOLOGISTS will notice with regret a paper bearing the above title in the late number of the *Journal of the Anthropological Institute*. The author appears to have taken up, without proper study, that difficult and dangerous line of argument, the comparison of historical names, and has naturally fallen into the network of delusive fancy which in past generations entangled Jacob Bryant and Godfrey Higgins. Modern philology has abundantly proved that slight, loose, and occasional correspondences in proper names are deceptive as evidence, even among languages of the same family, much more among languages of different families. It is a fair sample of the present paper, that it argues an affinity between the peoples of the Old and New Worlds on the basis of a connection between various names of the Deity, among which are the Russian *Bog*, the Manchoo *Ab-ka*, and the Hottentot *Tyopa*. The special purpose is to prove that nations are shown by their names to trace descent from an ancestor called *Ad*—"*Adam*, or Father *Ad*." Thus "the great Hamitic race of *Akkad*" is interpreted by the aid of Welsh *ach*—root, lineage," so as to mean "sons or lineage of *Ad*;" and the name of *Ta-ata*, the Polynesian First Man, is "that of the mythical ancestor of the Adamites, reversed, however, and with the addition of *ata* (*aka*), spirit"! It is obvious, though unaccountably overlooked in the paper, that two of the clearest cases of the theory may be found near home. The descent of two nations from Father *Ad* is perfectly recorded by ourselves, when we call the representative of one a *Paddy*, clearly *Ap-Ad* (from *Ap*, "used in the sense of son"), while the other's Adamite ancestor is commemorated by calling his descendant a *Taffy*.

It is not necessary to give the name of the author of this unlucky paper. Everybody is liable to slips, great or small; and a man may have done work worth doing in one line, but turning suddenly to another, may come to grief utterly. But the Council of the Anthropological Institute should have consulted their own interest and that of their contributor by declining to print the present essay. It is the duty of a learned society to examine even a hasty and ill-considered idea brought forward by one of its members, but not to put it on public record against themselves and him. M. A. I.

The Segmentation of Annulosa

IN the extract from his Address to the Entomological Society, given in *NATURE*, February 29, Mr. Wallace remarks that Mr. Spencer's views have not been so much as once alluded to in the

discussion of the Origin of Insects. The general question of the Annulosa obviously includes that of Insects, and I therefore desire to correct this statement, and to refer your readers to a paper by me on *Chetogaster* and *Eolosoma*, published in the "Linnean Transactions," vol. xxvi. (read Dec. 1867), in which I have more than alluded to Mr. Spencer's views, and have offered some suggestions on the morphology of the head, and as to the unisegmental Annulose ancestor. Mr. Wallace quotes from this paper in reference to *Chetogaster*, though from the context it would appear that he is quoting from Professor Owen.

Since the researches which have rendered Mr. Wallace's name one of the first among living zoologists have not led him into practical anatomical and embryological studies, I may venture to add one or two strictures upon his statements relating to such matters. In the first place, those who are engaged in the study of insect embryology are not ignorant of Mr. Spencer's or similar views; the wide-spread study of his works in England and America, and of Haeckel's general morphology in Germany, is sufficient guarantee of this. But even if it were as Mr. Wallace supposes, he has not, in the extract given in *NATURE*, shown at all how Mr. Spencer's views on aggregation are to influence the study of the embryology of insects. Of course, the general theory of somites has immense importance in all studies relating to the Annulosa, but in what way the particular form of it, due to Mr. Spencer, can influence conclusions drawn from the observation of the manner in which insects develop from the egg, Mr. Wallace does not explain. Whether, admitting or denying the truth of Mr. Spencer's or Prof. Haeckel's views, it would be equally conceivable, did the observed facts point in either direction—that the ancestry of insects is to be traced to a simple nauplius-form or to a multi-segmental Annelid-like progenitor, the question of segmentation is not finally settled, though it is largely elucidated by the doctrine of Mr. Spencer. It is no doubt an instructive point of view to take—that segmentation is an arrested production of zooids, but it is equally true that the production of zooids is an exaggerated segmentation. We have no grounds for assuming the one more than the other as the essential process; they are both phases of the same process. The fact appears to be that in certain masses of organised matter, on their reaching a certain limit of growth, "polarities," which were hitherto held in one system, break up into two and so on. The simplest case of this is cell-division, but whether the systems separate entirely, as in simple fission, or remain associated, as in the cleavage of the egg and in the segmentation of the Annulosa, depends on another factor, a cohesive or integrating force proper to the growing mass.

In the present state of knowledge upon the subject, the assumption adopted and held of so much importance by Mr. Wallace—that the Vertebrata do not exhibit a segmentation of the same kind as that of the Annulosa, is by no means justified. Though much of their jointed iterative structure may probably be due to that kind of adaptation which Mr. Spencer so justly distinguishes as "superinduced segmentation," yet that there is a fundamental bud-segmentation, or segmentation of growth identical with that of Annulosa, is in the very highest degree probable. And even as to the Chiton, which Mr. Wallace quotes from Mr. Spencer as quite certainly an example of superinduced segmentation, I think that had he examined the grounds for making such a statement, he would have hesitated. The larva of Chiton is identical with that of an Annelid, and its segmentation makes its appearance in the same way. Why should there not be segmented molluscs? It is necessary most constantly to bear in mind, when considering this matter of segmentation, the possibility of the partial or complete obliteration of segmental characters due to tertiary aggregation, and their modification in most various ways in the evolution either of an individual or of a group.

Further, as to Mr. Wallace's expressions with regard to the segmentation of insects. From what was said above as to the relation of segmentation and zooid production, it follows that the conception of segmentation is erroneous which leads to ascribing to insects peculiar physiological or psychical properties on account of their being composed of "a number of individualities fused into one." This expression should not be allowed to lead to wider conclusions than those it formulates. As a matter of fact, insects are not a number of individualities fused into one, but rather one individuality partially (and as a reminiscence rather than actually) broken up into many, this partial breaking up being due to the mechanical properties of its tissues at a certain period of development.

If, by the "spiracles" of Annelids, Mr. Wallace means the segmental organs, it should be clearly stated that the identity of these with the tracheæ of insects has not yet been in any way proved. The comparison of the mode of development of these two sets of organs is just one of the points upon which embryologists are now at work.

Lastly, the researches of the last fifteen years do not, I venture to submit, lead to the conclusion adopted by Mr. Wallace, that the parthenogenesis of the higher Annulosa is analogous to or identical with gemination as opposed to sexual reproduction or digenesis, but to the conclusion which is exactly opposed to this, namely, that it is identical with digenesis in all particulars but the absence of the male element.

E. RAY LANKESTER

Adaptive Coloration, Phosphorescence, &c.

No one who has watched a very young hare stealing from a green covert to brown soil, and observed its cunning movements there when alarmed, can for a moment doubt the value of colour as a protection to the higher animals.

The remarks by Mr. E. S. Morse in *NATURE* of last week bring to my recollection a good instance (among invertebrates) which occurs on the reddish granite of Cobo Bay, Guernsey. There *Trochus lineatus* especially abounds on the bare parts of the rocks between tide-marks; and every observer must be at once struck by the remarkable fitness of the mollusk for its peculiar site.

Mr. Darwin in truth says, * "It would not, for instance, occur to any one that the perfect transparency of the Medusæ or jelly-fishes, was of the highest service to them as a protection; but when we are reminded by Hæckel that not only the Medusæ, but many floating mollusca, crustaceans, and even small oceanic fishes, partake of this same glass-like structure, we can hardly doubt that they thus escape the notice of pelagic birds and other enemies;" but he makes no mention of the gorgeous colouring of some of these swimming jellies, nor is there any allusion to their remarkable property of phosphorescence. The transparency of the British Salpæ does not prevent their being attacked by sea-birds, which hover in multitudes over them, masses of Medusæ and other Hydrozoa, and a few minute fishes.

If instead of promulgating the visionary idea that the abysses of the ocean depended for their light on phosphorescent animals, the dredger in the *Porcupine* had applied the notion that the various luminous marine animals used their light to attract each other, so that the most luminous might have a better chance of continuing the race, they would have been able to say more in its favour, without, at least, running counter to established facts.

W. C. MCINTOSH

The Aurora of February 4 †

AN aurora of a very unusual splendour for the latitude was seen here on Sunday evening February 4, 1872. The sky, extending in azimuth over 197° from N.E. to nearly W.S.W., was generally illuminated. The brilliance of the glow varied considerably in different directions from time to time during the night. On the south horizon there was a bright bluish segment of light, whose position in azimuth and brilliance varied slightly from time to time. The streamers were well seen, and their convergence towards the point to which the south pole of a magnet is directed could be most distinctly traced. The streamers extended at about nine o'clock to the constellation Orion, and Sirius was well within the auroral glow. With a spectroscope I saw one bright line in the spectrum of the auroral light, but the spectrum was too faint to allow of any successful attempt to determine the refrangibility of the light. Unfortunately our magnetical equipment is such that I can give no information respecting the extent of the magnetical disturbance at the time. The aurora was seen as far north as Bloemfontein, latitude 29° 8' south. A faint aurora was seen here in October 1870, but no such aurora as that of February 4, 1872, appears to have been visible for at least fifty years. The aurora was well seen over a large portion of the colony, and considerably frightened the natives.

Royal Observatory, Cape of Good Hope, Feb. 19

* "Descent of Man," vol. i., p. 322.

† Not, however, Mr. Jeffreys

‡ Communicated by the Astronomer Royal.

SEEKING your account of the aurora of February 4 in NATURE of the 22nd, reminds me that on the evening of the 4th I was riding from Cambridge to Coldwell, in Ohio, and between six and seven o'clock saw a most brilliant display of auroral light in the southern quarter of the sky. Brilliant streamers shot up past the zenith, while the whole southern portion of the sky was brightly illuminated with a corruscating rose-coloured light.

A. J. WARNER

Morse on Terebratulina

I HAVE just read the very kind notice of my paper* in the pages of your journal from the pen of Mr. E. R. Lankester. I hasten, however, to remove one impression conveyed in the following sentence, respecting the opinions I hold as to the Annelidan affinities of the Brachiopods:—

"We are not sure whether Mr. Morse adheres to this startling proposition."

I trust the long delay in publishing the results of my studies on this interesting class will lead no one to suppose that I have yet seen reason to modify the position I took two years ago regarding their position in the animal kingdom. On the contrary, continued investigation has brought out many new points of interest, and now I hope, ere my paper is published, to present the embryology of some one of them.

I had studied our native Terebratulina, its structure, as well as its early stages, and through the kindness of Prof. Verrill, had studied *Discina levis* (upon which I hope soon to publish).

Mr. Lankester, as the author of many valuable memoirs requiring much skill and patient labour, will fully appreciate the time and care necessary in work of this kind.

As to my being unduly impressed at the sight of living Lingula, I may say, in justice to myself, and my friends will testify to it, my opinions were fully formed before I ever saw Lingula at all. With the caution that is requisite for every one, if he does not wish to supplement his paper with a correction of errors, a way of doing things altogether too frequent in this country, I deemed it important to study living Lingula before publishing. It was impossible for me to go half-way round the world for it. And as three specimens of another species have been found on the coast of North Carolina, I determined to go there. A trip of nearly a thousand miles brought me to its waste of drifting sands.

Thoroughly convinced as to the correctness of my views, and these views of sufficient strength to convince my co-labourers, Mr. Lankester will understand my enthusiasm when, after a week's fruitless search under a blazing sun, and an almost hopeless task, I found Lingula, not as we have always supposed attached by its peduncle, but living in the sand, precisely like many tubicolous worms, building a true sand tube, and when liberated from its crawling and burrowing by means of its setae, and with all these welcome characters it should greet me with red blood. Not that I lay great stress on any one of these characters, but having made my deductions from the most common form, Terebratulina, one can readily understand the bearing of such unexpected characters in this little Lingula.

Mr. Lankester will admit that the Vermian lumber-room has some orderly compartments; into one of those I place the Brachiopods far away from all Molluscan odours.

The distinguished naturalist, Prof. Steenstrup, informs me that he has long taught his classes at the University of Copenhagen that the Brachiopods were true Annelids, and that my views are thoroughly endorsed by him. "To him, therefore, and not to me as had been supposed, belongs the priority of this discovery."

I only ask a little patience till my complete paper is published on the Brachiopods as a division of Annelida, in which I shall give appropriate figures, and my reasons in full for the position I have taken.

EDWARD S. MORSE

Salem, Mass., U.S.A., March 14

On the Colour of a Hydrogen Flame

WHEN hydrogen and oxygen are burned together, it is well known that the flame produced is almost non-luminous; it always, however, exhibits an unmistakable blue tinge.

The small illuminative power is generally referred to the "absence of solid particles." This view, it appears to me, draws a too rigid line of demarcation between the atoms of carbon in an ordinary gas-coal flame and the atoms of hydrogen in that of

the oxyhydrogen. The cause of the phenomenon does not depend so much on the *solidity* as it does on the time of oscillation of the particles which constitute the flame. Water particles in all their states of aggregation preserve the same time of oscillation—extra red; hence a hydrogen flame should be perfectly invisible whatever may be the "solidity" or density of its particles.

But the flame is not invisible, and, what is still more remarkable, the colour which it does exhibit is found to belong to the most refrangible end of the spectrum. To explain this strange phenomenon, it appears to me that it is necessary to invoke a state in the ether particles similar to that which Helmholtz has shown to exist in air; and which is this:—A tuning-fork "vigorously struck against a pad emits the *octave* of its fundamental note." Now, the first overtone of a tuning fork is produced by vibrations about 6½ times as rapid as the fundamental; the octave, therefore, is not an overtone of the fork—it is produced solely in consequence of the fact that the initial disturbance is great in proportion to the distance of the air particles from one another, secondary waves being produced whose periods are twice as rapid as those of the fundamental.

The amplitude of the particles in a hydrogen flame is known to be very great, and hence it seems probable that an effect may result from the disturbance thus created in the ether, analogous to that in the case of air, *i.e.*, associated with the fundamental vibrations of the hydrogen flame we have their *octave*, which would obviously be within the visual range, and correspond very closely, if not *exactly*, with the colour actually observed.

Should this surmise prove correct we have plainly an easy means by which we can determine the wave-length of those extra-red rays which are absorbed by water.

A. G. MEEZE

Hartley Institution, Southampton, March 26

P.S.—May not the great *actinic* power of the electric light be due in a great measure to the secondary waves produced by the magnitude of the disturbing force?

VESTIGES OF THE GLACIAL PERIOD IN NORTH-EASTERN ANATOLIA

ATTENTION was drawn to this subject in a lecture given on March 25 at the Royal Geographical Society by the Eastern traveller Mr. W. Gifford Palgrave, at present British Consul for the northern coast of Asia Minor. The facts which he mentioned had been principally observed by him during a tour on duty to the interior about two years ago; and the line of route lay from the town of Trebizond on the sea coast to that of Erzingian on the Upper Euphrates.

The phenomena themselves were divided into two classes: the one referable to the highlands which he had then traversed, the other to their marginal region.

These highlands are situated on or near the 40th parallel of latitude, and extend between the 37th and 44th of longitude, east and west; their average breadth being about fifty miles, and their elevation varying from 3,000 to 9,000 feet above the sea. They constitute the great watershed of Eastern Anatolia; the rivers to the south of them flowing into the Persian Gulf, and those to the north into the Black Sea. To the west is the basin of the Halys, to the east that of the Caspian.

The road leading across this plateau towards Erzingian, mounts up to it by a defile named "Ketcheh-Dereh," or "Goats' Valley." Here, at a height of about 5,400 feet above the sea, Mr. Palgrave came on the lower extremity of a large moraine, piled up to a height of more than twenty feet, and broad in proportion. Following it for a distance of nearly half a mile, he found that when it had reached between 400 and 500 feet higher up the slope, it forked into two lesser branches, continued each a good way further into the rising undulations of the table-land.

The plateau itself bore every mark of having lain under a thick ice-coating; its eminences and irregularities all bearing the "moutonnée" character impressed by glacial action; while it was also frequently strewn with detached

* "Early Stages of Terebratulina."

boulders and pieces of rock, scratched and scored with the unmistakable lines that glaciers alone produce. These phenomena he observed to be repeated, or rather continued, throughout the highland, which he crossed three times at intervals, including above 100 miles of its length.

About the midmost of the plateau stands a solitary, dome-like eminence, nearly 8,000 feet above the sea level, and rounded off in every direction. On the west side of this mountain, now known as "Yelish Dagh," near its base, Mr. Palgrave found a second moraine, consisting of a single stone bank five or six hundred yards in length, stretching down to a valley below: its higher extremity was at about 6,500 ft. And lastly, at the great cleft about fifty miles distant, called the Cherdakh Pass, and leading downwards from the plateau into the Euphrates valley, he observed a third moraine, larger than either of the two former, and extending over a slope of fully 2,000 ft., its base being only about 4,500 ft. above the sea.

From these and similar indications, Mr. Palgrave conjectured that during the glacial period an ice-cap of fifty miles in average breadth, and many hundred in length, must have covered this table-land from a height of 6,000 ft., or rather less, upwards; while some of the more advanced glaciers may have reached to a far lower level, seemingly 4,000 ft.

Such were the most remarkable surface-phenomena of the plateau itself. But on its margin, whether north or south, and connected with it, were other indications of an analogous character. These consisted in the traces afforded by broad and deep ravines and neighbouring river beds, much too wide for the streams that flow through them; all affording evidence of a past epoch when the water supply was on a far more copious scale than it is now. Thus the valley of the Euphrates itself, which takes its rise in this very plateau, is, in its evenly-scooped extent of three and even four miles across, out of all proportion with the comparatively little and feeble stream that now meanders along it; and the same must be said of most of the aqueous modifications imprinted in the lower mountain ranges, and in the plains at their feet.

But of all the phenomena of this kind none is more remarkable than that inspected by Mr. Palgrave near the sea-end of the great valley by which the river, once Pyxartes, now "Deyermend-Dereh," or "Mill Stream" enters the Euxine, close by Trebizond. This river, whose waters are derived from the central table land, is now so shallow as to be readily fordable at almost every season of the year, and brings down with it just enough pebble and soil to form a little bar at its mouth. Half a mile, however, from the present beach the river valley, here about a third of a mile in width, is in its greater part crossed by a huge bar of rolled stones, at least forty feet in eight, and eighty or a hundred yards in thickness at its base, evidently formed here by the joint action of river and sea. The stones, many of which are of great size, belong to Jurassic or Plutonic formations, such as compose the plateau inland, whereas the coast-rock is entirely volcanic. But the flood of water requisite to bring them from such a distance is now wholly wanting. Nor can its diminution be ascribed to the extirpation of forest wood, for the mountain chain is still as densely clothed with trees as it could ever have been in remote times; nor yet to an alteration in the course and dip of the valleys that unite to send their supplies hither, for there is no trace of any great geological change hereabouts within the epoch to which the bar itself is referable. One only cause there could have been capable of furnishing so impetuous a stream, namely, the periodical melting of great masses of ice and snow on the mountains behind, now unusually bare of snow from June till November, and absolutely denuded of anything approaching to a glacier. When these icy reservoirs ceased the abundance of the river ceased also, leaving the bar alone as a monument of its former strength.

T. P.

THE INHABITANTS OF THE MAMMOTH CAVE OF KENTUCKY

CRUSTACEANS AND INSECTS

THE following account of the inhabitants of the Mammoth Cave of Kentucky is abridged from the *American Naturalist*. To the courtesy of the editors of that journal we are further indebted for the accompanying illustrations:—

After the adjournment of the meeting of the American Association for the Advancement of Science, held at Indianapolis in August last, a large number of the members availed themselves of the generous invitation of the Louisville and Nashville Railroad Company, to visit this world-renowned cave, and examine its peculiar formation and singular fauna.

The cave is in a hill of the subcarboniferous limestone formation in Edmondson County, a little to the west and south of the centre of Kentucky. Green river, which rises to the eastward in about the centre of the State, flows westward, passing in close proximity to the cave, and receiving its waters, thence flows north-westerly to the Ohio. The limestone formation in which the cave exists is a most interesting and important geological formation, corresponding to the mountain limestone of the European geologists, and of considerable geological importance in the determination of the western coalfields.

We quote the following account of this formation from Major S. S. Lyon's report in the fourth volume of the "Kentucky Geological Survey," pp. 509, 510:—

"The sinks and basins at the head of Sinking Creek exhibit in a striking manner the eroding effects of rains and frost—some of the sinks, which are from 40 ft. to 190 ft. deep, covering an area of from 5 to 2,000 acres. The rim of sandstone surrounding these depressions is, generally, nearly level; the out-cropping rocks within are also nearly horizontal. Near the centre there is an opening of from 3 ft. to 15 ft. in diameter; into this opening the water which has fallen within the margin of the basin has been drained since the day when the rocks exposed within were raised above the drainage of the country, and thus, by the slow process of washing and weathering, the rocks which once filled these cavities have been worn and carried down into the subterranean drainage of the country. All this has evidently come to pass in the most quiet and regular manner. The size of the central opening is too small to admit extraordinary floods; nor is it possible, with the level margin around, to suppose that these cavities were worn by eddies in a current that swept the whole cavernous member of the subcarboniferous limestone of western Kentucky; but the opinion is probable that the upheaving force which raised these beds to their present level at the same time ruptured and cracked the beds in certain lines: that afterwards the rains were swallowed into openings on these fractures, producing, by denudation, the basins of the sinkhole country, and further enlarging the original fractures by flowing through them, and thus forming a vast system of caverns, which surrounds the western coalfield. The Mammoth Cave is at present the best known, and therefore the most remarkable."

So much has been written on the cave and its wonders, that to give a description of its interior would be superfluous in this connection, even could we do so without unintentionally giving too exaggerated statements, which seems to be the natural result of a day underground, at least so far as this cave is concerned, for, after reading any account of the cave, one is disappointed at finding the reality so unlike the picture.

We are indebted to Prof. Alexander Winchell, of the University of Michigan, for the following abstract of his views concerning the formation of the cave:—

"The country of the Mammoth Cave was probably dry land at the close of the coal period, and has remained

such, with certain exceptions, through the Mesozoic and Cænozoic ages, and to the present. In Mesozoic times, fissures existed in the formation, and surface waters found

FIG. 1.—*Anthomyia*.

their way through them, dissolving the limestone and continually enlarging the spaces. A cave of considerable dimensions probably existed during the prevalence of the

FIG. 2.—*Phora*.

FIG. 4.
Aëlops hirtus.

FIG. 3.—*Anophthalmus Tellkampfi*.

continental glaciers over the northern hemisphere. On the dissolution of the glaciers, the flood of water which swept over the entire country, transporting the materials

FIG. 5.—*Hadenocnus subterraneus*.

which constituted the modified drift, swept through the passages of the cave, enlarging them, and leaving deposited in the cave some of the same quartzose pebbles which

characterise the surface deposits from Lake Superior to the Gulf of Mexico. Since the subsidence of the waters of the Champlain epoch, the cave has probably undergone comparatively few changes. The well, 198 ft. deep, at the farther end of the cave, shows where a considerable

FIG. 6.—*Campodea*.

volume of the excavatory waters found exit. The Mammoth Dome indicates probably both a place of exit and a place of entrance from above. So of the vertical passages in various other portions of the cave."

We believe that the views of Prof. Winchell are in har-

FIG. 7.—*Anthrobia monmouthia*.

mony with those of the other eminent geologists of the party; and when it is considered that the geologists of this excursion stand in the front rank of the most eminent scientific men of the world, their views upon this interesting subject are well worthy of attention.

FIG. 9.—*Spirostrephon Copei*.

With these general remarks on the cave, we give a brief account of its interesting fauna, comprising representatives of the insects and crustaceans. No molluscs or radiates have as yet been discovered; but the lower forms of life have been detected by Tellkamp, who col-

lected several species belonging to the genera *Monas*, *Chilomonas*, and (?) *Chilodon*.

Representatives of all the grand divisions of the insects and crustaceans have been found in this cave, and if no worms have yet been detected one or more species would undoubtedly reward a thorough search.

We will enumerate what have been found, beginning with the higher forms. No Hymenoptera (bees, wasps, and ants) or Lepidoptera (moths) are yet recorded as being peculiar to caves. The Diptera (flies) are represented by two species, one of *Anthomyia* (Fig. 1), or a closely allied genus, and the second belonging to the singular and interesting genus *Phora* (Fig. 2). The species of *Anthomyia* usually frequent flowers; the larvæ live in decaying vegetable matter, or, like the onion fly, attack healthy roots. It would be presumptuous in the writer to attempt to describe these forms without collections of species from the neighbourhood of the cave, for though like all the rest of the insects they were found three or four miles from the mouth, yet they may be found to occur outside of its limits, as the eyes and the colours of the body are as bright as in other species.

Among the beetles, two species were found by Mr.

Cooke. The *Anopthalmus Tellkampfi* of Erichson, a Carabid (Fig. 3), and *Adelops hirtus* Tellkamp (Fig. 4), allied to Catops, one of the Silphidae or burying beetle family. The *Anopthalmus* is of a pale reddish horn colour, and is totally blind; * in the *Adelops*, which is greyish brown, there are two pale spots, which may be rudimentary eyes, as Tellkamp and Erichson suggest. No Hemiptera (bugs) have yet been found either in the caves of this country or Europe. Two wingless grasshoppers (sometimes called crickets) like the common species found under stones (*Ceuthophilus maculatus* Harris), have been found in our caves; one is the *Hadenæus subterraneus* (Fig. 5 nat. size) described by Mr. Scudder, and very abundant in Mammoth Cave. The other species is *H. stygia* Scudder, from Hickman's cave, near Hickman's landing, upon the Kentucky river. It is closely allied to the Mammoth Cave species. According to Mr. Scudder the specimens of *H. stygia* were found by Mr. A. Hyatt "in the remotest corner of Hickman's Cave, in a sort of a hollow in the rock, not particularly moist, but having only a sort of cave dampness. They were found a few hundred feet from the sunlight, living exclusively upon the walls." Even the remotest part of that

FIG. 3—*Acanthocheir armata*.

cave is not so gloomy but that some sunlight penetrates it.

The other species is found both in Mammoth Cave, and in the adjoining White's Cave. It is found throughout the cave, and most commonly (to quote Mr. Scudder) "about 'Martha's Vineyard' and in the neighbourhood of 'Richardson's Spring' where they were discovered jumping about with the greatest alacrity upon the walls, where only they are found, and even when disturbed, clinging to the ceiling, upon which they walked easily; they would leap away from approaching footsteps, but stop at a cessation of the noise, turning about and swaying their long antennæ in a most ludicrous manner, in the direction whence the disturbance had proceeded; the least noise would increase their tremulousness, while they were unconcerned at distant motions, unaccompanied by sound, even though producing a sensible current of air; neither did the light of the lamp appear to disturb them; their eyes, and those of the succeeding species (*H. stygia*), are perfectly formed throughout, and they could apparently see with ease, for they jump away from the slowly approaching hand, so as to necessitate rapidity of motion in seizing them."

The Thysanurous Neuroptera are represented by a

species of *Machilis*, allied to our common *Machilis variabilis* Say, common in Kentucky and the middle and southern States. So far as Tellkamp's figure indicates, it is the same species apparently, as I have received numerous specimens of this widely distributed form from Knoxville, Tennessee, collected by Dr. Josiah Curtis. It was regarded as a crustacean by Tellkamp, and described under the name of *Triura cavernicola*.† Hemistook the labial and maxillary palpi for feet, and regarded the nine pairs of abdominal spines as feet. The allied species, *M. variabilis* Say, is figured in vol. v. pl. 1, figs. 8, 9.

* In Erhardt's cave, Montgomery Co., Virginia, Prof. Cope found "four or five specimens of a new *Anopthalmus* the *A. pusio* of Horn, at a distance of not more than three hundred feet from its mouth. The species is small, and all were found together under a stone. Their movements were slow, in considerable contrast to the activity of ordinary Carabidae." *Proc. Amer. Phil. Soc.* 1869, p. 178.

† Prof. Agassiz, in his brief notice of the Mammoth Cave animals, does not criticise Tellkamp's reference of this animal to the crustacea; and so eminent an authority upon the articulates as Schidde remarks, while "Dr. Tellkamp's account affords us no means of forming any conclusion as to its proximate relations," that, however, it "appears to belong to the order of Amphipoda, and to have a most remarkable structure." Tellkamp's figure of *Machilis* is entirely wrong in representing the labial and maxillary palpi as ending in claws, thus giving the creature a crustacean aspect, and, indeed, he describes them as true feet!

An interesting species of *Campodea*, of which the accompanying cut (Fig. 6) is a tolerable likeness, though designed to illustrate another species (*S. staphylinus* Westw.) was discovered by Mr. Cooke. Both the European and our common species live under stones in damp places, and the occurrence of this form in the water is quite remarkable. The other species are blind, and I could detect no eyes in the Mammoth Cave specimen.

A small spider was captured by Mr. Cooke, but afterwards lost; it was brown in colour, and possibly distinct from the *Anthrobia monmouthia* Tellk. (Fig. 7), which is an eyeless form, white and very small, being but half a line in length. The family of Harvest men is represented by a small white form, described by Tellkamp under the name of *Phalangodes armata* (Fig. 8), but now called *Acanthocheir armata* Lucas. The body alone is but half a line long, the legs measuring two lines. It should be borne in mind that many of the spiders, as well as the Thysanura, live in holes and dark places, so that we could naturally find them in caves. So, also, with the Myriopods, of which a most remarkable form (Fig. 9 front of head) was found by Mr. Cooke three or four miles from the mouth of the cave. It is the only truly hairy species known, an approach to it being found in *Pseudotremia Vudii* Cope. It is blind, the other species of this group which Prof. Cope found living in caves having eyes. The long hairs arranged along the back seem to suggest that they are tactile organs, and of more use to the thousand legs in making its way about the nooks and crannies of a perpetually dark cave than eyes would be. It was found by Mr. Cooke under a stone.

Prof. Cope has contributed to the "Proceedings of the American Philosophical Society" (1869, p. 171) an interesting account of the cave mammals, articulates, and shells of the middle states. He says that "myriopods are the only articulates which can be readily found in the remote regions of the caves (of West Virginia) and they are not very common in a living state." The *Pseudotremia cavernarum* which he describes, "inhabits the deepest recesses of the numerous caves which abound in Southern Virginia, as far as human steps can penetrate. I have not seen it near their mouths, though its eyes are not undeveloped, nor smaller than those of many living in the forest. Judging from its remains, which one finds under stones, it is an abundant species, though rarely seen by the dim light of a candle even after considerable search. Five specimens only were procured from about a dozen caves." The second species, *P. Vudii* Cope, was found in Montgomery Co., and he thinks it was not found in a cave. Prof. Hyatt informs me that he saw near the "Bottomless Pit" in Mammoth Cave, a brownish centipede-like myriopod, over an inch in length, which moved off in a rapid zigzag motion. Unfortunately, he did not capture it.

A. S. PACKARD, JUN.

(To be continued)

NOTES

WE have received information of a most munificent act on the part of that veteran in Geological Science, Sir William E. Logan, in supplementing, by the handsome gift of 18,000 dols., the sum of 2,000 dols. given by him and his brother, Mr. Hart Logan, last year towards the endowment of the Chair of Geology in McGill University, Montreal. The "Logan Chair of Geology" will be at once a commemoration of Sir William's name in connection with the higher education of our colonists, and a means of perpetuating the teaching of the Science for which he has done so much, as well as of securing the training of a succession of young men who may worthily follow up his investigations in the wide field of Canadian Geology. Principal Dawson, who at present occupies the Chair of Geology, will be the first "Logan

Professor," and it is intended that the endowment shall, as soon as possible, be made the means of relieving him from the teaching of some other portions of natural science, in order that he may more fully devote his time to Geology and Palæontology.

PROF. HUXLEY is now on his way home to England, having been last heard of from Naples. His health is very greatly restored by his absence from work, and the effects of the Egyptian climate.

DR. M'NAB, Professor of Botany and Geology at the Royal Agricultural College, Cirencester, has been appointed Professor of Botany to the Royal College of Science and Art, Dublin, in the place of Prof. Thiselton Dyer. The appointment is a good one, on which we congratulate the Science and Art Department. The Lectureship at the Cirencester College is now vacant.

THE death of the Swiss palæontologist, M. Pictet de la Rive, Professor in the Academy of Geneva, which we noticed last week, took place on the 15th ult. at the age of sixty-two, and was occasioned by fever induced by a severe accident.

DR. GEORGE BURROWS, F.R.S., has been re-elected President of the College of Physicians.

PROF. HUXLEY was defeated by a small majority by Lord Neaves in the election for the Rectorship of St. Andrew's University. Prof. Sylvester was also, we regret to say, unsuccessful in his candidature for the School Board for Marylebone. We understand, however, that there will shortly be another vacancy on the Board, when we trust Science will once more put in its claim.

THE Brighton Aquarium was formally opened to the public on Saturday last.

It has been decided to give a private view and evening reception in the Picture Galleries of the London International Exhibition of 1872 before the 1st of May, to which distinguished foreigners and holders of season tickets will be invited.

AT Rugby Mr. Wilson and Mr. Seabroke have tried the experiment of giving regular lectures on Astronomy to a class consisting of volunteers from the school and residents in the town. Note-books were shown up and corrected, and an examination held at the end. About seventy attended, twenty being members of the school; thirty showed up note-books, and eighteen presented themselves for examination. Advocates of women's education will be pleased to learn that the two best note-books were written by girls, and that in the examination, which was a stiff one (we have seen the paper), girls held the second, third, and fifth places. The proceeds are for buying books for the Temple Observatory.

AN organisation, entitled the Bloomington Scientific Association, was instituted at Bloomington, Illinois, in 1871, having for its object the diffusion and popularising of science in that State. The officers are Prof. B. S. Perry, Mr. R. H. Holder, Dr. Vasey, and Mr. J. A. Jackman. The society has already a large number of members, and meets frequently.

THE great depression of temperature during November and the early part of December, was followed by an extraordinarily long period of more than three months' remarkably mild weather. For the ninety-seven days from December 13 to March 18, Mr. Glaisher's Greenwich tables, recorded weekly in the *Gardener's Chronicle*, show that the temperature was above the average on eighty-nine, and below the average on only eight days, the mean excess for the whole period being 5°·1. During the whole of this period the thermometer fell below the freezing point on four nights only, viz., January 15 and 16, and March 10 and 11; the lowest temperature recorded being 28°·3 Fahr. on the first and last of these dates.

February, it will be seen, was entirely free from frost, the minimum for that month being $32^{\circ}4$, on the 28th. The warmest period was from March 1 to 8, when the maximum temperature ranged each day from $57^{\circ}11$ to $60^{\circ}8$. It will be interesting to know whether so long a period of exceptionally high temperature, including fifty-three consecutive days entirely free from frost, has ever been recorded before in the depth of winter. On March 19 the average temperature of the day fell below the mean, and continued so for nine days, till the 27th. The minimum temperature for March was on the 21st, $26^{\circ}2$ Fahr., being the lowest recorded since Dec. 9. There were nine frosty nights in March, against the two in the whole of the two preceding months. For the week ending March 26 the mean temperature was 34° , or 16° lower than the mean for the week ending March 7.

A CORRESPONDENT of *The Blue* strongly urges the desirability of the formation of a Natural History Society at Christ's Hospital; and the editor of that magazine promises his assistance to the proposal. We heartily wish it success.

THE proposed Act for appropriating the Yellowstone Park for public purposes (to which we recently referred), has passed the Congress of the United States. The following are extracts from the Bill:—"That the tract of land in the territories of Montana and Wyoming (as already described) is hereby reserved and withdrawn from settlement, occupancy, or sale under the laws of the United States, and dedicated and set apart as a public park or pleasuring-ground for the benefit and enjoyment of the people. That said public park shall be under the exclusive control of the Secretary of the Interior, whose duty it shall be, as soon as practicable, to make and publish such rules and regulations as he may deem necessary or proper for the care and management of the same. Such regulations shall provide for the preservation from injury or spoliation of all timber, mineral deposits, natural curiosities, or wonders within said park, and their retention in their natural condition. The Secretary may, in his discretion, grant leases for building purposes for terms not exceeding ten years, of small parcels of ground, at such places in said park as shall require the erection of buildings for the accommodation of visitors; all of the proceeds of said leases, and all other revenues that may be derived from any source connected with said park, to be expended under his direction in the management of the same, and the construction of roads and bridle paths therein. He shall provide against the wanton destruction of the fish and game found within said park, and against their capture or destruction for the purposes of merchandise or profit." Such a step in the interest of science deserves more than a passing recognition from this side the water.

THE *British Medical Journal* prints the following admirable reply to the extraordinary article which appeared in the *Saturday Review* of the 16th ult., on Dr. Liebreich's lecture on "Turner and Mulready," which we gave last week:—"It is not, of course, always to be expected that *Saturday Reviewers* should have a very profound knowledge of their subjects; but it might be thought advisable that an analysis of an optical argument should not be publicly undertaken by a gentleman who is ignorant of the first rudiments of the subject, and so little acquainted with even the alphabet of its language as the gentleman who discusses, in the last *Saturday Review*, the visual defects of Turner and Mulready. He pronounces a 'verdict of not proven' on Mr. Liebreich's argument; and his fitness for appreciating a discussion of the effects of yellow discoloration of the lens, occurring with advancing old age, on Mulready's perception of colour, may be estimated by the following sentence: 'Let us suppose a person to put on a pair of yellow spectacles. The effect is assumed to be, and we think correctly, that the yellow in a landscape or in a picture, unless extra strong, would

be scarcely recognised; and that the blues also, unless very decisive, would be neutralised. The consequence seems to follow, that the painter would throw *ultra force* into both yellow and blue; though against this supposition it must not be forgotten that the spectacle or the crystalline lens, as the case may be, would discolour precisely in the same degree the tones in nature and the pigments on the palette.' The italics are ours. There is scarcely a word in this astonishing statement which is not entirely a mistake. It was not assumed, but it is known, that, seen through a yellow glass, the yellows in a landscape are seen relatively more strongly, while the blues are partly neutralised. It was not assumed that the effects of viewing a landscape and a picture through a yellow lens or glass are the same; but, on the contrary, it was stated, as the result of experiment, that they are entirely different. The retina becomes presently so far accustomed to the yellow medium, that the strong lights reflected from blue surfaces in nature overpower the yellowness of the medium, and the blues of a landscape are presently but little neutralised. The reflections from pigments, poor imitations as they are, at the best, of nature, have not the same power; a large part is neutralised by the yellow glass or lens; and to produce with pigments, on a canvas, blues which satisfy his eye as comparable with those which he sees in nature, the painter—who in old age has the pigment-yellowness of senile change in the lens—employs much deeper blues than he would have done in youth, or than impress youthful eyes as representing the natural tints truthfully. That is why, on Liebreich's theory, Mulready, in painting the same picture in old age which he had painted in middle life, introduced ultramarine into the flesh tints—painted a linen smock of the brilliancy of a glittering silk; and that is the key which he affords to the prevailing excess of purple tints which the official catalogue describes as characterising the latest works of this great artist. The great master himself was, in his later life, dissatisfied for this reason with the colour of his earlier works; he thought them too brown, and used to warn his pupils to paint with stronger blues, especially in the grey shadows.'

IN a letter addressed by von Heuglin to Middendorff, of the St. Petersburg Academy, we find the fullest details of the explorations instituted by that eminent traveller during the past summer in the Nova Zembla seas. In this he remarks that the original plan included a visit to the mouths of the Obi and Yenisei, perhaps even extending to the island of New Siberia. This, however, was found to be impracticable on account of unseasonable weather, as it was not till the 6th of August that they reached the Straits of Matotschkin. Up to that time they had met with no ice; but after passing the straits to the east there was very much drift ice from the sea of Kara so as almost to bar their way. Finding that the northern coast of the island was entirely embargoed by ice, they turned to the south, and in passing visited the Straits of Kostin and the Nechwatowa, then Waigatsch, and finally arrived at the Straits of Jugorsky on the 1st of September. Here the expedition did not make any better progress than in the Straits of Matotschkin, and fearing that they might be shut in by the ice for the winter, they returned to their starting-place. Among the more important results of the voyage were numerous soundings and measurements of deep-sea temperatures, as also various geographical determinations; while large collections of specimens of natural history were brought together. Among these the most interesting was the discovery of two different species of lemming in Nova Zembla, and it was thought possible that in Southern Nova Zembla still a third species might be met with. The same animal was also found in Spitzbergen. Numerous birds were obtained in Nova Zembla and Waigatsch; among them the Mandt's Guillemot. Of fishes, some species of cod, cottus, and salmon were obtained, and about one hundred species of plants.

INDIAN papers give the following additional accounts of the aurora of February 4.—Such a phenomenon has not been observed in the Punjab, or perhaps in India, within the memory of man, and in consequence the remarks made by the natives and others born in the country were rather curious. A curious circumstance took place at Raikote. About 100 Kooka families turned out in the most excited state, and commenced those wild demonstrations from which the name *Kooka* is derived. The men tore off their turbans, unloosed their hair, and began dancing and waving their arms about, and shouting that this was a token that Ram Singh had returned to his home. They were much disappointed to learn that they were mistaken. At Sealkote many thought that the red in the sky was the reflection of the blaze of some hill forest on fire, and one individual at Jhelum suggested that it must be caused by some volcanic eruption in the Himalayas. In another place a commissariat officer was thrown into an agony of terror, thinking it was his haystacks on fire. A correspondent, writing from Madhopore, says:—"On the night of the 4th instant, between 11 and 12 o'clock, there appeared in the sky a clear bright light, like fire, which lasted about fourteen minutes. It was so bright that we were able to see even the minutest objects; owing to its red colour the river appeared as though it were blood. The atmosphere for days has never been clear of clouds, and it seems as if a storm were portending. The lightning injured some natives on the 5th inst."

A CORRESPONDENT suggests that the memory of Dr. Priestley will not be so worthily honoured by a bad statue as by a thoroughly well-appointed School of Science to be called "The Priestley Institution," or whatever other name be thought fitting. Science is much needed to supplement the technical skill employed in the industries of the Black Country, and is not in that district so well provided for as to render the establishment of such a school unneedful. Or if that undertaking be thought too vast, he proposes the endowment at the Newcastle College or elsewhere of a scholarship of Physical Science, to provide young aspirants from the Midland Counties with opportunities of scientific practice and culture. Or if this suggestion do not find favour, possibly the ingenuity of the committee can devise some scheme of a similar sort, so that thus the funds subscribed for this memorial may be used for science.

WE note the proposed formation of a National Swimming Baths Company (Limited), to provide good and cheap swimming baths in the Thames.

ACCORDING to a communication to the Geological Society of Hungary, the remains of a man, associated with post-tertiary remains of mammalia, together with a stone hammer, have lately been discovered in the loess deposits of Hungary, in the neighbourhood of Brux, in Bohemia. These were in nearly a complete condition. The cranium strongly resembles in its characteristics the well-known fragment from the Neanderthal, although differing in certain peculiarities mentioned in the article. The skeleton was found lying with the head raised, in a sand-bed of diluvial age, at a depth of two feet from the surface.

IN making an excavation on the banks of the Amoor River, *Harper's Weekly* states that a stone axe of nephrite, or jade, and beautifully finished, was found at a depth of about three feet. This fact is the more interesting as it bears upon the question in regard to the celebrated stone-tipped arrows which were used by the primeval inhabitants of Manchuria as late as the twelfth century. It was with arrows winged with eagles' feathers and tipped with nephrite points that this people paid their tribute to China while they were under its dominion. The precise locality of nephrite in Manchuria is unknown, although it is stated by some to have been on a mountain to the north-west of that country.

THE Perthshire Society of Natural Science held its Annual Meeting on March 7, when Colonel H. M. Drummond Hay was elected president in the room of Dr. Buchanan White, who has held the office for five years. This enterprising society must be congratulated on the work it has done in the exploration of the natural history of the county, and in the commencement of the publication of so valuable a work as the *Fauna Perthensis*, and the promotion of so useful a periodical as the *Scottish Naturalist*. Botany seems, however, up to the present time, to have been neglected by the Society, which is to be regretted in a county with so rich and interesting a flora. The Society has also held "a meeting for investigation into the qualities, as articles of food, of certain Perthshire animals," commonly known as a "Frog-supper." Among the articles of the bill of fare were—Pâté d'Ecureuil, Matelot de Grenouille, Alouette à la Crapaudine, Ecureuil au naturel.

AN Act passed by the Governor-General of India in Council in October last, with a view to provide for the ultimate adoption of a uniform system of weights and measures of capacity throughout British India, has been laid before the House of Commons. The Act directs that the unit of weight shall be a "ser," equal to the French kilogramme, and the unit for measures of capacity, a measure containing one such ser of water at its maximum density, weighed in a vacuum. Other weights and measures of capacity, to be authorised under this Act, are to be integral multiples or sub-multiples of their units, the sub-divisions to be expressed in decimal parts unless otherwise ordered. When proper standards have been provided for verification of these weights and measures to be used by any Government office, municipal body, or railway company, the Governor-General in Council may direct that the weights and measures as authorised shall be used in dealings by such office, body, or company. The local Government may prepare tables of the equivalents of other weights and measures in terms of the weights and measures so authorised.

DR. W. LAUDER LINDSAY announces as in preparation, "Mind in the Lower Animals," a popular exposition of those traits in the habits of animals that illustrate their possession of the higher as well as the lower faculties of mind, as it exists in man. Dr. Lindsay has already written extensively on the subject in the *Journal of Mental Science* and the *British and Foreign Medico-Chirurgical Review*.

THE second enlarged and improved edition is published of Dr. O. W. Thomé's "Lehrbuch der Botanik," intended especially for elementary classes of botany in gymnasia and public schools. Although some portions of the work, especially the systematic, are open to exception, yet it presents the elements of the different departments of botanical science in a more compact form, and at a lower price (3s.) than probably any other work. It is illustrated by nearly 900 woodcuts.

MR. SHIRLEY HIBBERD has in the press a volume entitled "The Ivy, a Monograph," which will shortly be published by Messrs. Groombridge and Sons.

A USEFUL catalogue is published at Ghent, entitled, "Nomenclature usuelle de 550 Fibres Textiles, avec indication de leur provenance, leurs usages," &c., by the conservator of the commercial-industrial museum in that city.

MESSRS. GROOMBRIDGE AND SONS are preparing a new edition, with coloured plates, of Mr. Lambton J. H. Young's "Sea Fishing as a Sport."

MR. B. S. LYMAN, mining engineer to the Public Works Department of the Government of India, reprints from the "Transactions of the American Philosophical Society" an account of the Punjab Oil Region, accompanied by a geological and topographical map.

ANNUAL ADDRESS TO THE GEOLOGICAL SOCIETY OF LONDON, FEB. 16, 1872

BY J. PRESTWICH, F.R.S., PRESIDENT

(Continued from page 433.)

It has been already mentioned that below a certain level permeable strata are necessarily always saturated and water-logged, and that any additional quantity added to this constant quantity cannot be held permanently. It follows that wherever, in all water-bearing strata, after allowing for any abstraction, usually but comparatively small, by wells, the surplus rainfall must, when the stratum is full, find its escape by natural means, *i.e.*, by means of springs. The power and size of these are necessarily dependent upon the dimensions of the strata by which they are supplied. In the gravel they are small, in the Lower Tertiary sands moderate; while in the Chalk they are very large. The permanence of the spring depends on the lithological character as well as on the dimensions of the strata. Thus, in sands, where the water can permeate the mass, the stores are large, and the delivery moderately quick; in Limestones, where the water is confined to cracks and fissures, the delivery is quick and not lasting, though often large; in rubbly Oolites, which are also practically porous, the springs are well maintained; while in Chalk, owing to the characters before named, the water-delivery is slow, and the springs are large and very permanent.

At the same time the storage-capacity increases with the resistance. Taking the extreme case of the Chalk, the transmission of the rain-water is so slow, that, on the chalk hills, it takes four or six months to pass from the surface to the line of water-level at the depth of 200ft. to 300ft., so that the heavy rainfall of winter is not felt in the deep springs until the summer, and Mr. Beadmore estimates that the minimum effect of a hot dry summer and autumn is not reached until at the end of about sixteen months, or that the storing-power of the chalk is of sixteen months' duration. To estimate this power, we have to take the height and extent of the hills, and to note the lithological characters of the permeable strata. If these latter are underlain by impermeable strata at above the level of the rivers in two adjacent valleys, then the base of the underground water-store will be coincident with the level of the impermeable strata, and its surface-line will rise, as it recedes within the hill, in proportion to the resistance offered to the water's escape by the character of the permeable strata, and it will thus form a curve between those two points, the height of which will vary in proportion to the rainfall. When, on the other hand, the permeable strata continue down to a greater or less depth beneath the surface of the adjacent rivers, then, as there is no underground escape for the stored water, the line of water-level in those permeable strata will rise to, and be always maintained at, the level of the rivers, and therefore all the additional supplies furnished by the rain must, after traversing the interior of the hills, find an escape along the bottom of the valleys, and by the side or in the bed of those rivers. In the dry upland valleys of the Chalk and Oolites, the underground water, dammed back by the streams in the nearest river-valley, passes under those valleys at depths varying with the resistance offered by the lithological character of the formation, and by the gradient of the valley as it runs into the hills.

When again, as in the case of the chalk downs and oolite hills, the exterior outcrop of the permeable strata rests on impermeable strata at a height above the river-levels, and in the other direction inwards they pass below similar levels, then the springs partake of the same divided character—the one smaller set flowing out on the sides of the hills, and the stronger and more lasting springs issuing, as it were, at the foot of the incline on the level of the rivers. In any case, it is the distance between the two points of escape that gives us one measure of storage. If the distance is reckoned by miles, then the rise of the water-level may be measured by tens of feet. It is highest when both the distance from the adjacent river-valleys, and at the same time the height of the hills is greatest. In some instances, the crown of the arch formed by it will rise to a height of from 60 ft. to 80 ft. above its chord.

This curve is subject to great fluctuation, varying according to the seasons and amount of rainfall. Mr. Clatterbuck has shown that, in the chalk hills of Hertfordshire, its height varies as much as 30 ft. or 40 ft. From the crown or centre of its summit it decreases at a rate varying generally from 3 ft. to 30 ft., or even more, per mile to all parts of the circumference. The

height of the arch and the breadth of the base-line, taken together, give therefore the head of water supplying the large springs of the Chalk—such as those of Chadwell, Hoddesdon, Otter, Carshalton, Leatherhead, Ospringe, and others. But, besides these, there are innumerable smaller ones, not so easily seen, flowing out on the sides, or in the beds of the rivers traversing the great permeable formations, as the many along the Thames from Greenhithe to Faversham, on the Upper Lea and its tributaries, and on the Medway and the Darent, where they traverse the chalk hills. This class of springs has especial geological bearings, which we shall hereafter have occasion to dwell upon.

The same general rules govern the springs of all the more varied strata of the upper part of the Thames basin, where, in place of the Cretaceous and Tertiary series, we have a series of Jurassic and Liassic strata. Omitting the drift or gravel beds, the following are the average dimensions, character, and superficial areas of each of these formations in that area:—

STRATA OF THE THAMES BASIN ABOVE WALLINGFORD

	Area. Square miles.	Average Thickness.	
		Permeable strata.	Impermeable strata.
Chalk (above Kingston 1047)	60	1000	—
Upper Greensands ...	62	100	—
Gault ...	129	—	130
Lower Greensands ...	23	200	—
Purbeck and Portland beds	46	60	—
Kimmeridge Clay ...	132	—	300
Coral Rag and grit ...	103	40	—
Oxford Clay ...	307	—	400
Great and Inferior Oolites...	327	450	—
Fuller's Earth ...	16	—	40
Lias ...	170	—	500

But although many of these water-bearing strata are of large dimensions and well stored in the upper part of the Thames basin, none of those below the Gault, except the Lower Greensand, are available for a well-supply at London. The Upper Greensand, so important in Wiltshire, is reduced to a few feet of comparatively impermeable argillaceous sands under London. The Oolitic series, so rich in springs in the district of the Cotswold Hills, have been ascertained to thin off as they range eastward; and Mr. Hull has shown that the inferior Oolite and underlying sands in particular die out, in all probability, under the Oxford clay about the centre of Oxfordshire. Even apart, therefore, from the discovery made at Kentish Town, we should now have excluded the Oolitic series as a possible source of supply to deep wells in the London district; although, as sources of springs' supplies, they contribute so important a share to the maintenance of the Thames. Few of those strata are, however, so homogeneous as the Chalk and the London Clay. The permeable formations often contain subordinate impermeable clays—seams which form water-levels of more or less importance, whilst the impermeable clays sometimes contain subordinate beds of sand or of rock which constitute small local water-bearing beds. It is for the geologist to assign its relative value to each of these subordinate features, and to distinguish the minor from the major sources.

Taking the Thames above Kingston, there is, according to Mr. J. D. Harrison, an area of 1,233 square miles of impermeable strata, and of 2,442 miles of permeable strata, and the mean annual rainfall in that district amounts to about 27 inches. From the impermeable strata the rain flows off immediately as it falls, and is carried at once to sea; whereas a large portion of that which falls on the permeable strata is, as we have shown, stored for a greater or lesser time, and discharged in perennial springs. It is these which give permanence to our rivers. The evidence taken before the Commission showed that the daily discharge of the Thames at Kingston, even in the driest season after weeks without rain, never falls below 350,000,000 gallons, while the average for the year gives, according to Mr. Simpson and Mr. Harrison, 1,353,000,000 gallons, or, according to Mr. Beadmore's longer observations, 1,145,000,000 gallons daily, the mean of 1,250,000,000 gallons being equal to a fall of about 8 in., or rather less than one-third of the annual quantity, the other two-thirds being lost by evaporation and absorbed by the vegetation. This seems the proportion usual under the like general conditions in these latitudes. M. Belgrand has shown, in "La Seine," that in the upper basin of the Seine there are 19,390 square kilometres of impermeable, and 59,210 of per

meable strata; and careful measurements have proved that the discharge at Paris is also equal to about one-third of the rainfall. The exact proportion of the rainfall passing into the different permeable strata, and given out again in the form of springs, has yet to be accurately determined. Mr. Harrison estimates it in the Thames basin at about one-sixth of the rainfall.

In districts where impermeable strata predominate, the total water delivery, therefore, will be greater; but it follows close upon the rainfall; whereas, where the permeable strata predominate, a large portion of the rainfall is stored in the hills, and its delivery is thereby spread over a greater or lesser period of time, according to the dimensions of those hills. This is well exemplified in the case of the basins of the Thames and the Severn, which latter is formed in large part by the slate rocks of Wales. The former has an area above Kingston of 3,670 square miles, with an annual rainfall of 27 inches; whereas that of the latter above Gloucester has an area of 3,890 miles, with an average rainfall of probably not less than 40 inches, and the mean daily discharge for the year is for the Thames of 1,250,000,000 gallons, and for the Severn about 1,600,000,000 gallons. Yet the summer discharge of the Thames averages 688,700,000 gallons daily, against 297,599,040 gallons of the Severn; and while the minimum discharge of the Thames in the driest seasons never falls below 350,000,000 gallons, that of the Severn falls below 100,000,000 gallons. Again, in the case of the Lea, where there is a still larger proportion of permeable strata, the daily discharge at Broxbourne for the year is, according to Mr. Beardmore, 108,000,000 gallons, while for the summer months it remains as high as 71,000,000, and in the driest seasons does not fall below 42,000,000 gallons.

Let us now look at one of the geological questions dependent upon the solvent action of the water on the strata it traverses. The analyses, made for the Commission by Drs. Frankland and Odling, of the waters of the Thames and its tributaries in the Oolitic and Chalk area, show that every 100,000 parts or grains of rainwater has taken up a quantity varying from 25.58 to 32.95 grains of solid residue, or an average of 29.26, which is equal to 20.48 parts or grains per gallon; another analysis of the Thames water at Ditton gives 20.78 grains per gallon of solid residue. It was also shown by Drs. Letheby and Odling and Prof. Abel that the unfitted waters of the Thames Companies, which take their supplies above Kingston, contained 20.82 of solid residue. If from the average of 20.68 we deduct 1.65 grain for organic and suspended matter, we have 19 grains of inorganic residue for every gallon of water flowing past Kingston. This is of course apart from the sediment carried down in floods. The ordinary monthly analyses, conducted by the same eminent chemists during the course of several past years, show that this quantity is liable to very little variation, the only difference being that it is somewhat larger in winter and less in summer.

Some general estimates have already been made by Profs. Ramsay and Geikie of the quantity of mineral matter carried down in solution by the Thames; but the more exact data supplied to the Commission enable us to make some additions to previous results. Taking the mean daily discharge of the Thames at Kingston at 1,250 million gallons, and the salts in solution at 19 grains per gallon, the mean quantity of dissolved mineral matter there carried down by the Thames every twenty-four hours is equal to 3,364,286 lbs. or 1502 tons, or 548,230 tons annually. Of this daily quantity about two-thirds, or 1,000 tons, consist of carbonate of lime, and 238 tons of sulphate of lime, while limited proportions of carbonate of magnesia, chlorides of sodium and potassium, sulphates of soda and potash, silica and traces of iron, alumina, and phosphates, constitute the rest. If we refer a small portion of the carbonates, and the sulphates and chlorides chiefly, to the impermeable argillaceous formations washed by the rain water, we shall still have at least 10 grains per gallon of carbonate of lime, due to the Cretaceous and Oolitic strata and Marlstone, the superficial area of which, in the Thames basin above Kingston, is estimated by Mr. Harrison at 2,072 square miles. Therefore the annual quantity of carbonate of lime carried away from this area by the Thames is 29,905 tons, or 797 tons daily, which gives 140 tons removed yearly from each square mile; or extending the calculation to a century we have 14,000 tons removed from each mile of surface. Taking a ton of chalk as equal to 15 cubic feet, this is equal to a removal of $\frac{1}{15}$ of an inch from the surface in the course of a century, so that in the course of 13,200 years a quantity equal to a thickness of about one foot would be removed from our Chalk and Oolitic districts.

I had some faint hope that this wear might furnish us with a rough approximate measure of time in reference to some of the phenomena connected with the Quaternary period; but we are not in a position to apply it. Those curious funnel-shaped cavities, called sand and gravel-pipes, so common in many chalk-districts, are the result of slow solution of the chalk by water at particular spots, whereby the superincumbent sand and gravel have been let down into the cavity so produced. Some of them are but a few feet deep, while others attain dimensions of 80 feet in depth by 15 to 20 feet in diameter at top, tapering irregularly to a point at bottom. It is, however, evident from the variation in size that the wear has been unequal; and it is also clear that the surface-waters have been conducted through these particular channels, where they existed, to the underground water-level, in preference to passing through the body of the chalk, so that the ratio of wear at these points is in excess. Nor can I see at present how otherwise to apply this measure. If it were possible to find a spot where the exposed surface of the chalk has been worn uniformly, and from the quantity of flints left after the removal of the chalk and the known distance apart there of the seams of flint, to determine the number of feet or inches removed, we might have a base to proceed upon, provided all the quantities remained constant. But such is not the case. Also, although the annual rainfall in the Thames now averages 27 inches, and has probably not varied much from this amount during the present period, it was evidently much greater during the Quaternary period; for I have elsewhere shown that, in the South of England and North of France the rivers of those areas with the same catchment-basins were of much greater size than at present; and Mr. W. Cunningham had before pointed out the same fact in the upper part of the basin with respect to some of the rivers of Wiltshire. M. Belgrand has made an attempt to estimate this quantity with reference to the Seine and its tributaries, and he arrives at the conclusion that, during the Quaternary (or, as he considers it, the Glacial) period, the rainfall was so heavy, that the discharge of the river was from 20 to 25 times greater than at present. I do not altogether concur in this view, but I can conceive that our rivers formerly were of five or six times the size they now are. This is an important element to be considered in all questions bearing on the denudation of land-surfaces.

There is yet another point which, although not in our direct field of research, yet depends so essentially upon the geological conditions we have discussed, and is one, in a public point of view, of such paramount importance, that I will, with your permission, say a few words on the subject. In an uninhabited country, the rain passes through the soil and issues as springs, bearing with it a certain proportion of mineral matter, and only traces of such organic matter as existed on the surface. This would be solely of vegetable origin, and the proportion would be in most cases very small. As man appeared, those conditions would be at first but little altered, for animal matters exposed on the surface rapidly decay and pass away in a gaseous form; but with increasing civilisation and fixed residences the necessity of otherwise getting rid of all refuse would soon be felt. I have shown how population followed the range of shallow permeable strata and the course of valleys, so as to obtain readily that indispensable necessity of life, a sufficient water supply. But with the art of well-digging it soon became apparent that, let the well be carried down but half way to the level of ground-springs, it would remain dry, and that then, so far from holding water, any water now poured into it would pass through the porous strata down to the water-level beneath, keeping the shallower well or pit constantly drained. So convenient and ready a means of getting rid of all refuse liquids was not neglected. Whilst on one side of the house a well was sunk to the ground-springs, at a depth, say, of twenty feet, on the other side a dry well was sunk to a depth of ten feet, and this was made the receptacle of house-refuse and sewage. The sand or gravel acting as a filter, the minor solid matter remained in the dry well, while the major liquid portion passed through the permeable stratum and went to feed the underlying springs. What was done in one house was done in the many; and what was done by our rude ancestors centuries back is continued to be the practice of their more cultivated descendants to the present day, with a persistency in the method only to be attributed to the ignorance of the existence of such a state of things among the masses, and to the ignorance of the real conditions and actual results of perpetuating such an evil—an evil common alike to the cottages of the poor and, with few exceptions, to the mansions of the rich.

Instances occur from time to time to point out isolated consequences of this pernicious practice, but I believe no one who has not gone into the geological question can realise its magnitude. It is not confined to one district or to a few towns or villages. It is the rule, and only within the last few years have there been any exceptions. The organised supply of water now furnished by companies in all large towns has, to a great extent, done away with the evil in those situations (though the root of the mischief has too often been left unextracted); but in villages and detached houses, great or small, it remains untouched and unchecked. Not a county, not a district, not a valley, not the smallest tract of permeable strata, is free from this plague-spot. It haunts the land, and is the more dangerous from its unseen, hidden, and too often unsuspected existence. Bright as the water often is, without objectionable taste or smell, it passes without suspicion until corrupted beyond the possibility of concealment by its evil companionship. Damage, slight in extent, or unimportant possibly for short use, but accumulative by constant use, may and does, I believe, pass unnoticed and unregarded for years. Nevertheless the draught, under some conditions, is as certain in its effects, however slow in its operation, as would be a dose of hemlock. Go where we may, we never know when the poisoned chalice may be presented to our lips. The evil is self-generating; for the geological conditions supplying our necessities lend themselves to its maintenance and extension. The knowledge necessary to remedy it is of very slow growth, and the too frequent want of that knowledge, or disregard of the subject, even amongst able architects and builders, is such that, without legislative enactment, I do not see how the evil is to be eradicated for many a long term of years.

This also is only one form of the evil—it is that where the water-bearing strata are thin and the wells do not exceed a depth of thirty feet. It was the one which prevailed in London, and in towns similarly situated, up to a very few years back. It even still lingers on in some private wells, and is moreover fostered among us by the bright-looking and cool water of too many of our public pumps; for not only does the ground still suffer from the effects of the original contamination, but also from much, almost inevitable, obnoxious surface-drainage, much gas escape, much rainfall on old open churchyards, which find their way to the one level of water supplying in common all these shallow wells. The evil still exists also, although to a less extent, in towns where the wells have to be carried to much greater depths; its effects varying according as the depth, and as the volume of the springs is to the sewage-escape; it is, however, only a question of degree.

But even our deeper and apparently inaccessible springs have not escaped contamination. As before mentioned, the underground water will, when tapped by artesian wells, rise to or above the surface, according to the relative height of the surface of the ground at the well, and of the outcrop of the water-bearing bed or beds, so that if the former is higher than the latter, or if by artificial means the line of water-level in a given area becomes lowered, then the surface of the water belonging to those great underground natural reservoirs will be established accordingly at a certain fixed depth beneath the surface. As each well deriving its supply in a stratum of this description represents a column of water communicating with one common reservoir, it follows that any cause permanently lowering the level of one well will tend to lower the level in the other wells in proportion to their number and distance. Further, it has been discovered that a well of this class can absorb a quantity of water equal to that which it can furnish; and as these wells give greater supplies than shallow wells, the absorbing wells of the same class are alike powerful in proportion to the others. The perverse ingenuity of man has here, again, taken advantage of these conditions to get rid of offensive waste waters by diverting them into such deep wells, whence they pass away in hidden underground channels, unseen and unsuspected, and mingle with those deep-seated water-sources feeding the artesian wells dependent upon them for their supply.

In Paris, where there are several alternating beds of permeable and impermeable strata, and the depth to reach them is not very great, this system of absorbing wells connected with factories became, until regulated by the municipality, very common, to the great injury of many of the underground springs. From this and the other causes before alluded to, a great number of shallow wells have there become so contaminated as to necessitate their abandonment. Our own system of surface-drainage is generally too good, and the depth to the lower water-bearing strata too great, to have rendered the use of such wells here

equally advantageous; nevertheless, I have reason to believe that they do exist, and that the sources even of our deep well-water supply in the Lower Tertiary Sands and in the Chalk are thus to some extent polluted and injured.

Nor do the great and perennial springs supplying our rivers altogether escape the evils arising from these obnoxious practices. On the high Oolitic ranges and amongst the undulating Chalk hills, the line of water-level is often so deep below the surface, that only in few cases are wells made—the population being generally dependent on rainwater for their water-supply. But this does not prevent the construction of dry wells for the disposal of sewage and refuse. It is true that the population in these hills is sparse—here and there a farm, a few cottages, and scarcely a village. Still as the ground is everywhere absorbent, and there are no streams even in the valleys (I am now speaking of the higher districts), every dwelling contributes its quota; for the rain and all liquid matter absorbed in these strata necessarily pass down to the great underground reservoirs of water feeding the springs thrown out in the deeper river-valleys. In these cases, however, the thickness of strata through which any liquid has to pass before reaching the line of water-level is such as to produce a more or less efficient filtration and complete decomposition; and as the injury caused is in proportion to the relative volumes of the water-sources and to the artificial additions, the great extent and dimensions of these water-bearing strata and the scanty population of such districts reduce it to a minimum.

Owing to these conditions, great as the evil is, experience teaches that it has, in some cases, its vanishing-point. It may be considered at its maximum in some of the wells of Paris; our own London shallow-well pumps follow next in order; in our river-waters away from towns it is but slight; in some of the springs of the Chalk and Lower Greensands it is hardly appreciable, while in the deep well-waters, especially those of Caterham and Grenelle, it sinks to the minimum attained by any potable waters, with the exception of rain-water. It is also a fortunate circumstance that the wonderful powers of oxidation possessed by air and water, and the powers of absorption and decomposition by soils and earths, are such as, even in the surcharged gravel-beds of London, to remove all the more offensive characters, and leave its spring-waters at all events limpid and bright; whilst the quick eddy, the moving ripple, the bright sunshine, the brisk breeze, the living organisms, are never at work in our rivers, destroying the almost inevitable accompaniments of the presence of man, and restoring the waters to that original state of purity so essential to his health and welfare.

It was on considerations of quantity of supply thus dependent on geological conditions, and of quality as dependent jointly on geological and artificial conditions, that the Commission was mainly so long and assiduously engaged. With regard to the character of waters as dependent on the geological nature of the strata, while the evidence showed that the waters flowing off hard and insoluble rocks were, from their much greater freedom from mineral matter, more economical for many domestic and manufacturing purposes, yet that for drinking purposes, waters such as those derived from our Chalk and Oolitic districts were, on the whole, as good and wholesome as those from any other sources; while as regards quantity and permanence, the conditions presented by a large catchment basin of a varied geological structure presented the most favourable conditions for the large and maintained supply so essential for a great city. And if, from any cause, it should at some future time be thought desirable to have a supply of a yet more assured and undoubted quality than a river supply, the large springs of the chalk and the Lower Greensand, or the great underground reservoirs of the most efficiently filtered water stored in those formations in Surrey and Herefordshire, might, I believe, be resorted to with advantage, by means of ordinary and artesian wells, as auxiliary sources of supply for domestic and drinking purposes, supposing the engineering difficulties connected with a double water-supply could be overcome—a difficulty which it, however, seems to me would possibly be less one of construction to our engineers than of cost to the public. But in a great health-question there are other considerations than these which are of more primary importance,

(To be continued.)

SCIENTIFIC SERIALS

Journal of the Franklin Institute, November 1871.—The editorial notes in this number are as usual very instructive;

amongst them we must notice Young's catalogue of the bright lines observed in the chromosphere of the sun, which have already reached a goodly number. Under Civil and Mechanical Engineering there are several useful and interesting articles, such as "On Woodworking Machinery," "On the Flow of water in rivers and canals," &c.—Prof. Cooke contributes the first of a series of papers "On the chemical theory of the Voltaic Battery." The present communication, however, deals with preliminary matters; it discusses molecules, atoms, and the quantivalence of elements. The paper which follows is "On some improvements in reflecting Telescopes," by J. A. Hill. The author proposes, in the first instance, to reflect the light from a movable plane mirror placed in the axis of the speculum, which receives the reflected rays; the convergent beam from the speculum passes through an aperture in the centre of the plane mirror, and can be received in a suitable eye-piece; no tubes are used, so that by this method it would be as easy to handle a mirror of 1,000 feet focal length as one of the same size of 50 feet focal length. The observer, too, would remain stationary, and need not be hoisted into mid-air.—Prof. Young continues his Spectroscopic Notes; this month's contribution is "on the construction, arrangement, and best proportion of the instrument, with reference to its efficiency." Under this head come the best angle and material for the prisms, the means of testing for flatness of surface and homogeneity of substance, and the number and arrangement of the prisms; there are also two other sections, "on dispersive efficiency and on luminous efficiency." A suggestion of a new form of chemical spectroscopy is given, the dispersive part of this consists of two prisms, which are each concave on one side, and are cemented to the convex object-glasses of the collimator and observing telescope. By this it is hoped to save both material and light.

THE *Geological Magazine* for March (No. 93) opens with a new species of *Rostellaria* (*R. Pricei*) from the Grey Chalk of Folkestone, by the editor, Mr. H. Woodward.—Mr. A. H. Green communicates a paper on the method of formation of the Permian beds of South Yorkshire, in which he discusses the general arrangement and palaeontology of these beds, and deduces from them a confirmation of Prof. Ramsay's theory that the Magnesian Limestone and associated beds of this part of England were formed in part by chemical precipitation in an inland sea.—Prof. H. A. Nicholson records the occurrence of the Cephalopod *Endoceras protiforme* Hall, in Britain; the specimen described and figured was discovered by the author in the mudstones of the Coniston series near Ambleside, a set of rocks in which scarcely any fossils, except Graptolites, have hitherto been found.—Mr. James Geikie gives a fourth paper on Changes of Climate during the Glacial Epoch, in the conclusion of which he sums up his views as to the sequence of climates at this time as follows:—1, A succession of alternate glacial and temperate conditions, but associated with the great Continental ice-sheets; 2, a temperate climate, with removal of the ice-sheets from low grounds; 3, a period of subsidence, with temperate climate, and much denudation of moraines; 4, a period of emergence, with arctic conditions, floating ice dispersing erratics, and deposition of clays with arctic mollusca; and, 5, a period of local glaciers in Britain and Ireland, with gradual amelioration of climate. In future papers the author proposes to discuss the cave-deposits and older river-gravels of England. The post-glacial geology and physiography of West Lancashire and the Mersey estuary, form the subject of an interesting paper, by Mr. T. Mellard Reade; and Prof. T. Rupert Jones and Mr. W. K. Parker give us the corrected nomenclature of the Foraminifera from the English Chalk, figured by the Rev. Henry Eley in 1859.—The number also contains an abstract of an address on subsidence as the effect of accumulation, read before the Liverpool Geological Society, by Dr. Charles Ricketts.

THE *Journal of Botany* for March contains only one original article bearing specially on British Botany, Notes on the British *Ramalina* (a genus of Lichens) in the Herbarium of the British Museum, by the Rev. Jas. Crombie. We find also, "On *Syma*," a new genus of triandrous *Liliaceae* from Chili, by Mr. J. G. Baker, with a plate; recent researches into *Diatomaceae*, by the Rev. E. O'Meara; and *Castanea vulgaris* grown in Southern China, by Dr. Hance. Mr. Carruthers contributes his important Review of the Contributions to Fossil Botany published in Britain in 1871; and the editor commences in this number a valuable list of the articles contained in the German botanical journals for January.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, Feb. 29.—"On the Relative Power of Various Substances in arresting Putrefaction and the Development of Protoplasmic and Fungus Life;" by Dr. F. Crace-Calvert, F.R.S.

March 14.—"Contributions to the History of the Osm Alkaloids," part iv., by Dr. C. R. A. Wright. "The Decomposition of Water by Zinc in conjunction with a more Negative Metal;" by J. H. Gladstone, F.R.S., and Alfred Tribe, F.C.S.

March 21.—"On some Heterogenetic Modes of Origin of Flagellated Monads, Fungus-germs, and Ciliated Infusoria," by Professor H. Charlton Bastian, F.R.S. In this communication Dr. Bastian announces results which, whilst confirming the previous observations of MM. Pinaud and Pouchet, considerably extend our knowledge concerning the heterogenetic changes liable to take place in the pellicle (composed of aggregated Bacteria) which forms upon an infusion of hay. He describes all the stages by which certain Fungi, Flagellated Monads, and Ciliated Infusoria are produced, as a result of changes taking place in the very substance of the pellicle. Most of the observations were made under a magnifying power of 1,670 diameters, and, although more extensive, are confirmatory of others published in NATURE, No. 35. Dr. Bastian says, "I now wish to describe other allied processes, and the means by which I am enabled to obtain, almost at will, either animal or vegetal forms from certain embryonal areas which are produced in the pellicle." The simplest mode of origin of Fungus-germs and Monads is thus described:—"The pellicle which formed on a filtered maceration of hay during frosty weather (when the temperature of the room in which the infusion was kept was rarely above 55° F., and sometimes rather lower than this) presented changes of a most instructive character. On the third and fourth days the pellicle was still thin, although on microscopical examination all portions of it were found to be thickly dotted with embryonal areas. Nearly all of them were very small; but a few areas of medium size were intermixed. The smallest were not more than $\frac{1}{32}$ " of an inch in diameter, and these separated themselves from the pellicle as single corpuscles; slightly larger areas broke up into two or three corpuscles; and others, larger still, into 4–10 corpuscles. In most of these small areas, the corpuscles were formed with scarcely any appreciable alteration in the refractive index of the matter of which they were composed; this simply became individualised, so that the corpuscles separated from the surrounding pellicle and from their fellows, still presenting all the appearance of being portions of the pellicle, and exhibiting from 4 to 10 altered Bacteria in their interior. In some cases the products of segmentation soon developed into actual flagellated Monads in a manner presently to be described; whilst in others they seemed to remain for a longer period in the condition of simple motionless corpuscles. Other solitary corpuscles or small areas began to form in the pellicle in precisely the same manner, though they speedily assumed a highly refractive and homogenous appearance. Why some should undergo such a change, and not others, seems quite impossible to say. One can only assert the fact, and add that these highly refractive ovoid corpuscles were, for the most part, more prone to produce Fungus-germs than Monads. Many of them soon grew out into dissepimented fungus filaments, which rapidly assumed the *Penicillium* mode of growth. The spores, which were abundantly produced in terminal chaplet-like series, were, however, small, homogenous, spherical, and colourless." In other cases Monads and Fungus-germs are produced from the pellicle in precisely the same manner as that by which they arise within the terminal chambers of certain Algae or Fungi—that is to say, they result from the segmentation of a mass of homogenous protoplasm.

In speaking of such a mode of origin of Monads, Dr. Bastian says:—"Contrasting with the very pale fawn-colour of the evenly granular pellicle, there were numerous areas of a whitish colour, refractive, and more or less homogenous. These areas differed very much in shape and size; some were not more than $\frac{1}{16}$ " in diameter, whilst others were as much as $\frac{1}{8}$ " in diameter. Their shape was wholly irregular. As in the instances previously recorded, the first appreciable stage in the formation of an embryonal area in the pellicle was a local increase in the amount of gelatinous material between the units of this portion of the pellicle, so that they became more distinctly separated from one another than in adjacent parts. Gradually these particles became less sharply defined, and at last scarcely visible, in the midst of

a highly refractive protoplasmic mass which began to exhibit traces of segmentation. Masses of this kind were seen, which had been resolved by such a process of segmentation into a number of spherical corpuscles about $\frac{1}{1000}$ in diameter. These were at first highly refractive, though they gradually became rather less so, and revealed the presence of two or three minute granules in their interior. In other adjacent areas, a number of densely-packed, pliant, and slightly larger corpuscles were seen actively pushing against one another. When they separated, they were found to be active ovoid specimens of *Monas lens*, about $\frac{1}{1000}$ in length, and provided with a vacuole and a rapidly lashing flagellum.

In other cases embryonal areas of the same nature were formed, which went through similar processes of segmentation; although the units produced, instead of developing into *Monads*, were seen to become transformed into brown vesicular bodies, which subsequently germinated into Fungus filaments. Whilst affirming that he is now able to determine pretty surely the occurrence of either one of these phenomena, Dr. Bastian says:—

"Experience has shown me, that, if an infusion has been heated for a time to 212° F., the pellicle which forms on its surface very frequently never gives rise to an embryonal area. If the infusion has been prepared at a temperature of 149° — 158° F., the embryonal areas which form will give origin to Fungus germs; whilst in a similar infusion prepared at 120° — 130° F., the embryonal areas, which seem at first to be in all respects similar, break up into actively moving *Monads*."

Dr. Bastian then proceeds to give an account of the origin of *Paramécia*, laying stress upon the fact that, in order to obtain such organisms, it is necessary to employ a filtered infusion made with cold water. His observations on this subject were, in the main, confirmatory of those of M. Pouchet. Thousands of egg-like bodies, varying in size from $\frac{1}{1000}$ to $\frac{1}{100}$, were seen developing throughout the whole substance of a thick pellicle. He says: "It seemed to me that the differentiation took place after a manner essentially similar to that by which an ordinary 'embryonal area' is formed. The small embryos did not appear to represent the earlier stages of large embryos; and it seemed rather that spherical masses of the pellicle of different sizes began to undergo molecular changes, which terminated in the production of *Paramécia* of a correspondingly different bulk. Just as in the previously described embryonal areas masses of different sizes began to exhibit signs of change, so also here, spherical portions of the pellicle, differing within the limits above mentioned, began to undergo other heterogenetic changes. This was first indicated by an increased refractiveness of the area (especially when seen a little beyond the focal distance); and almost simultaneously a condensation of its outer layer seemed to take place, whereby the outline became sharply and evenly defined. At this stage an actual membrane is scarcely appreciable, and the substance of the embryo (when examined at the right focal distance) scarcely differs in appearance from the granular pellicle of which it had previously formed part. So far as it could be ascertained, the individual embryos did not increase in size, although they went through the following series of developmental changes. The contained matter became rather more refractive, and the number of granules within diminished considerably, whilst new particles after a time seemed gradually to appear in what was now a mass of contractile protoplasm. These new particles were at first sparingly scattered, though as they were evolved they continued to grow into biscuit-shaped bodies, which sometimes attained the size of $\frac{1}{1000}$. All sizes were distinguishable; and many of them moved slowly amongst one another, owing to the irregular contractions of the semi-fluid protoplasm in which they were embedded. Gradually the number of homogeneous biscuit-shaped particles increased; and at last a large vacuole slowly appeared in some portion of the embryo. It lasted for about half a minute, disappeared, and then, after a similar interval, slowly reappeared. Much irregularity, however, was observed in this respect. The next change that occurred was the complete separation of the embryo from the cyst which it filled, and the commencement of slow axial rotations. These rotations gradually became more rapid, though they were not always in one direction. The mass became more and more densely filled with the large biscuit-shaped particles, and at last the presence of cilia could be distinctly recognised on one portion of the revolving embryo. Then, as M. Pouchet stated, the movements grew more and more irregular and impulsive, so as at last to lead to the rupture of the thin wall of the cyst—when the embryo emerged as a ciliated and somewhat pear-

shaped sac, provided with a large contractile vesicle at its posterior extremity. . . . On emerging from the cyst, all the embryos, although differing somewhat in size, were of the same shape. This closely corresponded with the description given of *Paramécium colodii* in Pritchard's 'Infusoria,' namely:—"Obovate, slightly compressed; ends obtuse, the anterior attenuated and slightly bent like a hook." Cilia existed over the whole body, though they were largest and most numerous about the anterior extremity. No trace of an actual buccal cleft could be detected; and (except in the posterior portion of the body, where a large and very persistent vacuole was situated) the organism was everywhere densely packed with the large, homogeneous, biscuit-shaped particles. For many days these most active Infusoria seemed to undergo little change, though afterwards the number of the contained particles gradually began to diminish, whilst the body became more and more regularly ovoid, and a faint appearance of longitudinal striation manifested itself, more especially over its anterior half. At the same time a very faint and almost imperceptible mass ('nucleus') began to appear near the centre of the organism; and when examined with a magnifying power of 1,670 diameters, a lateral aperture (mouth) $\frac{1}{1000}$ in diameter was seen, which was fringed by short active cilia, arranged like the spokes of a wheel. These peculiarities correspond very closely with those of an embryo *Nassula*. Very many were seen with similar characters; and multitudes existed in all conditions intermediate between this stage and that of the simpler organism which first emerged from the cyst."

Dr. Bastian concludes by saying:—

"It will, of course, be seen that the phenomena which I have described as taking place in the 'proliferous pellicle' may be watched by all who are conversant with such methods of investigation. We do not require to call in the aid of the chemist; we need exercise no special precautions; the changes in the pellicle are of such a kind that they can be readily appreciated by any skilled microscopist."

"Just as I have supposed that living matter itself comes into being by virtue of combinations and re-arrangements taking place amongst invisible colloidal molecules, so now does the study of the changes in the 'pellicle' absolutely demonstrate the fact that the visible new-born units of living matter behave in the manner which has been attributed to the invisible colloidal molecules. The living units combine, they undergo molecular re-arrangements; and the result of such a process of heterogenetic biocrisis is the appearance of larger and more complex organisms; just as the result of the combination and re-arrangement between the colloidal molecules was the appearance of primordial aggregates of living matter. Living matter is formed, therefore, after a process which is essentially similar to the mode by which higher organisms are derived from lower organisms in the pellicle on an organic infusion. All the steps in the latter process can be watched; it is one of synthesis—a merging of lower individualities into a higher individuality. And although such a process has been previously almost ignored in the world of living matter, it is no less real than when it takes place amongst the simpler elements of not-living matter. In both cases the phenomena are essentially dependent upon the 'properties' or 'inherent tendencies' of the matter which displays them."

Mathematical Society, March 14.—W. Spottiswoode, F.R.S., president, in the chair.—The President made a statement to the effect that it had been desirable to apply for a Charter, and that he had taken the requisite steps for ascertaining the right mode of procedure. The proposal made by the President being unanimously agreed to, S. M. Drach for his present to the Society of two early and interesting works by Vieta and Ubaldi respectively.—The papers read were:—Prof. Clifford, "On a new expression of Invariants and Covariants by means of alternate numbers;" Hon. J. W. Strutt, "On the Vibrations of a gas contained within a rigid spherical cone." The former paper was concerned with methodical "Vorlesungen über die complexen Zahlen und ihre Functionen," by Dr. Hermann Hankel (1867). In the latter paper the problem discussed was one referred to in a paper on the "Theory of Resonance," Phil. Trans., 1871. It is the only case of the vibration of air within a closed vessel which has hitherto been solved with complete generality. A result arrived at was that the pitch is about a fourth higher for the sphere than it is for a closed cylindrical pipe, whose length is equal the diameter of the sphere.—

Mr. A. J. Ellis, F.R.S., communicated a question which had been forwarded to him by Prof. Haldeman, of Columbia, Pennsylvania, U.S., "The number of lines in a rhymed stanza being given, how many variations of rhyme-distribution does it admit of, suppose no line to be left without a rhyme?"

Victoria Institute, March 18.—Mr. Charles Brooke, F.R.S., in the chair.—Dr. Bateman on "Darwinism tested by recent Researches as to the Localisation of the Faculty of Speech." Having called attention to Mr. Darwin's statement, that the difference between man and the higher animals was only one of degree, and not of kind, he proceeded to show that such could not be the fact, and instanced the faculty of articulate language, a distinctive attribute of which there was no trace in the ape or other animals. After defining articulate language, he demonstrated that it was exclusively man's prerogative, and there was no analogy between it and the forms of expression common to the lower animals. He then stated that it had been thought that a particular part of the brain was the seat of language, and, if it were so, the Darwinian might contend that, as there was a certain similarity between the brain of man and of the ape and other animals, that they had the germs of the faculty. He then cited many cases which had been brought under the notice of German, French, American, English, and other surgeons, to show that even where various portions of the brain had been injured or destroyed, the faculty of speech remained. He concluded by stating that the faculty of articulate speech seemed to be an attribute, the comprehension of which was at present beyond us.

GLASGOW

Geological Society, February 8.—Sir William Thomson, LL.D., was elected president; Messrs. E. A. Wünsch, John Young, and James Thomson, F.G.S., vice-presidents.—Professor Young, the retiring president, delivered an address on "Rock Formations in relation to Geological Time." He concluded by expressing the pleasure he felt in resigning the chair to one so eminent in the walks of science as Sir William Thomson, whose contributions to theoretical geology had been of the utmost importance.—The President, in taking the chair, briefly thanked the members for the honour they had conferred upon him, and hoped he might be of some service to them in the prosecution of geological inquiry.

DUBLIN

Natural History Society, March 6.—Professor E. Perceval Wright, president, in the chair.—The President delivered his inaugural address. He gave an interesting account of the history of the society from its commencement in 1838, when their meetings were held in Suffolk Street, and the opening address delivered by Mr. O'B. Bellingham. "There were then 104 members, and in 1840 the number had increased to 150. In 1844 the museum so increased that Mr. M'Coy was appointed curator, and he in 1845 laid a catalogue of the Irish animals in the museum before the society. This catalogue was printed and appended to the report for 1845-46. During these years many records of species new to Ireland were made. Very many valuable and interesting papers on zoological subjects were read. Many of these are to be found in full in the *Annals and Magazine of Natural History*. It is strange in looking over some of these to be reminded how great has been the development of some branches of natural science since they were written. Friends of many of us here—friends still living—many of them by no means yet full of days, yet wrote before the developmental stages of the crustacea were known, and could write of Spongillia as undoubtedly allied to the Diatomacea. About 1851 a few students in college, including myself, determined to form the University Natural Science Association, which is now amalgamated with the present society. Ere ceasing to speak of the College Society, let me pay a passing tribute to the memory of those who were our strong support, and who freely and generously held out to us that helping hand, and who have now left us for ever—Robert Ball, W. H. Harvey, A. H. Haliday, and A. Furlong; nor would it be seemly to forget all the encouragement and assistance given to us by the authorities of the College and the Regius Professor of Physics, or the loss we sustained when Allman, our Professor, counsellor, and friend was, by a hard fate, moved to succeed Forbes in Edinburgh."

NEWSPAPER SCIENCE

WHETHER some knowledge of Science or some love for scientific truth will ever penetrate the masses, may well be questioned when we read such an article as the following, which appeared in the daily paper boasting the largest circulation in the world, and which we reprint almost entire as a curiosity of newspaper literature:—

"What is a Joule?—or who is he, if a Joule is a human being, and not a vegetable—a weapon of offence, or something to drink, or a Phantom? And if Joule be human, why did he not consider that human reason is fallible, and human patience exhaustible, when he penned, or got somebody else to pen, a maddening article which has appeared in the *Nautical Magazine*, from which we gather that the transformations of energy are in their nature similar to the operations of commerce; but with this difference, that in thermodynamics the relative values never vary. This, it seems, is the universal theorem of a Joule; and a red-hot poker must always bear the same relation to sixpence as the contents of a tea-kettle at boiling point bear to a five-pound note. . . . Under the new dispensation the sovereign, 'to which all other forms of energy can be referred,' is to be an unit of heat. On the obverse is stamped 'Joule's equivalent,' and on the other side is inscribed 772 foot-pounds. One unit of heat is the amount required to raise the temperature of one pound of water one degree, and the equivalent for this coin is 772 foot-pounds of work—that is, the work required to be expended to raise one pound weight 772 feet. . . . But what is the new 'Joule's equivalent' to be made of?—cobwebs, leather, or fresh butter?—and who wants to raise a pound weight 772 feet? As a problem of proportion, the theory is, of course, philosophical enough; but it would be just as easy to fix a unit of cold as well as a unit of heat; and, under any circumstances, until Joule comes into the open and tells us who he is, what he means, and when his equivalents are to be put into circulation, society, we fear, will decline to recognise a sovereign as a Joule, or thirty shillings as a Joule and a half."

Now, with the mental condition of the man who could pen such an article as this we have nothing to do; he may go on writing according to his lights every day of the week, and no one but his own friends need interfere to stop him. But there are one or two considerations which arise from the perusal of it not without their importance.

In the first place, bearing in mind the contempt for Science so often apparent in the public utterances of men of high calibre—instances occur to us as we write, and probably will to our readers, of men of the highest culture in literature or art, who never allude to scientific work or to scientific teachers without a scarcely disguised sneer at the inferior part which they play in the national economy—we may, after all, be content that Science is alluded to at all in a paper possessing so large a circulation. The next consideration is one to which we attach the highest importance.

Surely it is now time that scientific men themselves should take a little more trouble than they do—we know it is asking a good deal from them—in the matter of bringing their own work, and the importance of it to the community, before such audiences as the daily papers afford. Were they to do this, the labours of our great

scientific teachers—our Huxleys, Tyndalls, and Carpenters—would be enormously lightened. If we hear of an attendance of several thousands at a penny lecture by Huxley at Manchester, or a Sunday afternoon lecture in St. George's Hall by Carpenter, we fancy a love of science is spreading with rapid strides; but the fact is that the strides are not so rapid as they might be, because the labourers on whom progress depends are so few and the area of their lecture work is restricted, whereas many newspapers, on the other hand, number their readers by hundreds of thousands. Until scientific men do this, we must be content with the present state of things. It is in no spirit of invidious comparison that we may remind our readers of the frequent extracts which appear in our columns from *Harper's Weekly*, a political and general paper of very large circulation in the United States, the scientific department of which, containing information of the highest value, is edited by one of the most eminent scientific men of America. But what is the present state of things with us? In the main it is one in which the public is informed of scientific work by others than the doers of the work; and the labour of classifying these writers is not difficult.

In the first place we have, we are thankful to say, a small though gradually increasing number whose labours leave nothing to be desired, who, being men of scientific culture themselves, take a pleasure in their work, and to whom the friends of Science in this country cannot be too grateful. As an illustration of the labours of this class of writers, designed to present to the non-scientific public an account of remarkable scientific phenomena, in popular and yet accurate language, we may refer to one of the most recent publications of this class, an article entitled "A Voyage to the Sun" in the March number of the *Cornhill Magazine*, which we commend to the notice of all aspirants after scientific-literary fame. The play of fancy which invests with an attractive grace a subject that would appear dry to many, is combined with a happy art of describing scientific phenomena in clear and exact language, in a manner that we have seldom seen equalled. It is impossible to overrate the labours of these gentlemen in the present condition of Science in England.

Secondly, we have a still larger class where the intention is good, but in which the culture, scientific and otherwise, is not so high. In the writings of these Science is apt to run wild: accuracy gives place to imagery, and the would-be learners, after an hour's attempt at gaining knowledge, rise from it, knowing rather less than they did before, and looking upon Science as a fearful and wonderful thing with which the less they have to do the better.

We have next a third class, composed of writers as widely different as the poles, but we place them together because the harm they both do is incalculable. The writer who is anxious to know what a "Joule" is may be taken as the type of one division. Grossly ignorant of all kinds of Science, it is nothing to him that he should bring it into discredit; he is doubtless paid for his work, and we need say no more about him. In the second division we find sometimes high culture, but the writing is not written for Science's sake. It is entirely a personal affair. The advancement of Science gives way to that of the individual and his friends, and any subject written upon is seen through a fog of personality and advertisement.

On the whole we prefer the author of "What is a Joule?" to such a man as this, because we believe he does less harm, and is less likely to mislead "able editors."

There is one grain of comfort even in the imbecilities and inanities of would-be humorous writers in newspapers, that at least they have woken up to the idea that a scientific discovery is worth laughing at. This is a step gained. Twenty years ago, even ten years ago, the name of even so distinguished a scientist as Dr. Joule would have been utterly unknown to the herd of newspaper writers. We must be thankful for even this much; and look hopefully forward to the good day coming when Science will take her place by the side of her sisters, Art and Literature, as equally deserving of popular culture.

GRISEBACH'S VEGETATION OF THE GLOBE

Die Vegetation der Erde nach ihrer klimatischen Anordnung: ein Abriss der vergleichenden Geographie der Pflanzen; von A. Grisebach. 2 vol. (Leipzig: Engelmann, 1872.)

THIS important contribution to a branch of the science which, since the publication of A. de Candolle's "Géographie Botanique" and the promulgation of the Darwinian theories, has been daily acquiring greater value in the minds of philosophical naturalists, is the result of long study and persevering accumulation of data on the part of the learned author. Prof. Grisebach had already, in the "Linnæa" for 1838, given his first views on the limitation of natural floras by climatological influences; and since 1840 he has, in his periodical reports on the progress of geographical botany, entered more or less into the principles and conclusions which he has successively entertained or matured. He now supplies us in these volumes with a methodical digest of the facts he has collected, and of the conclusions he would draw from them. The result is a rich store of materials, which future investigators of the subject must necessarily have recourse to, and the arrangement adopted is perhaps the one best calculated to illustrate that branch of it which is more especially indicated by the title, the influence of climate and physical conditions on the stations and areas of species. But to the general naturalist the value of the work as a book of reference is much diminished by two great deficiencies; there is no summary of the conclusions he would draw from the facts he has detailed, and no index to enable the reader to turn to any individual fact, argument, or deduction, which may have struck him in the perusal of above 1,200 closely printed pages.

The question of the Origin of Species is not entered into, for the author believes that acknowledged facts prove nothing more than the production of varieties through climatological or other influences, but that "however interesting speculations on the genetic connections of organisms may appear, we abandon the territory of facts when we indulge in conjectures on the origin of more widely separated forms or races, of species, genera, or families of plants or animals." "That the limits between a species and a variety are not always to be strictly defined, is no reason," he observes, "why we should ascribe to both an identical process of formation, or that we should regard the forces by which the gradual variations

of forms are effected as the only ones by which the multiplicity of nature has been produced."

As far as we have been able to collect the professor's views, his idea seems to be that, whatever may have been its origin, every species now existing on the globe was at some given (or uncertain) time "produced" in "one particular spot, the centre of the species, from whence it has, from the natural tendency to multiplication inherent in every organised race, spread in every direction where its progress has not been checked by extraneous causes, generally by climatological or other physical opposing influences, sometimes by the mere struggle with competing races. Wherever a considerable number of species appear to have had their centres within a limited area, that area is termed a centre of vegetation (*Vegetations-centrum*); where the migration of plants from one or more centres is limited by physical obstructions, by mountain chains, seas, adverse climate, &c., the space thus enclosed is the province (*Gebiet*) of a natural flora. For the "centres of vegetation," the author had originally made use of the term "centres of creation" (*Schöpfungs-centren*), which he has now abandoned on account of the objections made to it as expressing some definite process of production. "I, at least," he adds, "under an act of creation, never understood anything else than the operation of certain laws of nature, the further knowledge of which is, as yet, withheld from us. Bentham prefers for the term 'centres of vegetation' that of 'areas of preservation,' when they remain in their original state, as in oceanic islands, a mode of expression to which we might well be reconciled" (p. 523). With regard to the term *Gebiet*, the natural translation would be *region*, but in this instance, with the facility enjoyed by Germans of adopting words of foreign languages, the word "Region" is made use of for areas limited by altitude within the *Gebiet*.

The twenty-four botanical provinces of natural floras which Grisebach had already sketched out in Petermann's *Mittheilungen* are here necessarily taken in detail, investigating under each one—(1) the climate; (2) the prevailing plant-forms; (3) the prevailing plant-formations; (4) the regions, chiefly as to altitude; and (5) the centres of vegetation included in the province. For the "plant-forms" he has carried out a classification founded on that of Humboldt, distributing plants under seven heads—(1) woody plants; (2) succulent plants; (3) climbers; (4) epiphytes; (5) herbs; (6) grasses—including sedges, reeds, &c.; (7) cellular plants: each one subdivided into minor groups. The "plant-formations" are tracts of country whose general aspect is characterised by their vegetation, such as forests, heaths, scrubs, deserts, cultivated tracts, &c.

The two provinces worked out with the greatest care, and for which the materials here collected are perhaps the most deserving of study, as being the most ample, and in both cases checked by the personal experience of the author, are the Forest-province (*Waldgebiet*) of the eastern continent (the greater part of Europe and temperate Asia), and the Mediterranean region; the one characterised by its vast uniformity, the other by its broken diversity; in both of which the complicated influences of climate, configuration, and soil, have been more carefully observed, recorded, and studied, than in any other quarter of the globe. The Mediterranean region is particularly instructive.

tive, not only from the richness of the flora, but from the large number of endemic monotypes (monotypic genera or sub-genera, or widely distinct species), confined to very restricted areas, and of disjointed species—identical species in widely dissevered areas. With regard to the species of narrowly confined stations, Prof. Grisebach believes that the considerations he has brought forward tell decidedly in favour of the conclusion "that monotypes and other rare organisms are not—or, at least, are not generally—to be regarded as the surviving remains of earlier creations, but as evidences of the productive power of the localities where they are now to be found, and from whence no means of migration are within their reach" (p. 364). He can, however, scarcely have paid attention to the various proofs recorded of the gradual reduction of the areas of several Mediterranean species, even within historical times, and still more since an immediately preceding geological epoch—that of the formation of the tufas of the south of France. He does not, indeed, seem to be aware of the instructive memoirs on this subject of Gustave Planchon (see Nat. Hist. Review, 1865, p. 202).

The "disjointed" species, on the other hand, appear to have puzzled Prof. Grisebach, as they have done and will continue to puzzle all speculators on Geographical Botany. Grisebach endeavours to reduce their number as much as possible; sometimes by the discovery of intermediate stations; then, again, by presumed colonisation through man or other agencies; or by showing that supposed identical forms in distant areas are really distinct species, and, therefore, beyond the scope of inquiries limited to the age of now-existing species. But yet, in the Mediterranean as in the Japanese provinces, he is obliged to admit some which occupy two limited areas separated by enormous intervals. Thus, although he supposes that the appearance of *Rhododendron ponticum* on the coast of Portugal may have been the result of introduction by the Arabs, that *Geum heterocarpum*, now only known from the mountain regions of S. Spain and of Elborus in Persia, may yet be found in intermediate localities; yet such suppositions, he admits, can in no way account for the disseverance of the Cedar in the Atlas, the Lebanon, and the Himalaya, or of the *Pinus excelsa* in the mountains of Macedonia and the Himalayas. Unwilling to admit that these and other instances (far more numerous than acknowledged by Grisebach) of widely dissevered stations may be the remains of once continuous areas, he suggests the possibility of the transference of seeds by winds, birds, &c. Birds are, indeed, probably powerful assistants in the migrations of plants. But the effect of winds has been much overrated, as shown for instance by Kerner in a paper recently published in the *Zeitschrift des Deutschen Alpenvereins*, and is made more of perhaps by Grisebach in the present work than by any other observer, and not always on the safest data. Thus he attaches (p. 389) great importance to an "unpublished memorandum of Berthelot's," that is to a label to a specimen of *Erigeron ambiguus*, bearing the words "cette composée, qui a quelques rapports avec les Conyza, est devenue très-commune sur toutes les côtes de Ténériffe après le dernier ouragan." This memorandum is amplified into "On the Canary Islands whose flora was so well known to him, this traveller saw, immediately after a violent hurricane, an annual *Synanthera*

(*Erigeron ambiguus*) which is generally dispersed over the Mediterranean flora, suddenly germinate and take permanent possession of the soil in the most diversified stations," the amplification thus including some half-a-dozen statements not contained in the original memorandum, adding especially the *propter hoc* to the *post hoc*. *Erigeron ambiguus* is one of those plants of which a single individual will produce seed enough to cover a considerable tract of country in the next following season, if favoured by a suspension of those counteracting influences which annually destroy all but one out of thousands, either in the state of seed or of the infant plant; and in Berthelot's memorandum we find no evidence either that the plant was not in the islands before the storm, or that the seed was actually brought by the storm, or that if so brought its germination and early growth were so exceptionally rapid, as to show the plant in an observable stage "immediately" after the storm. The inquiry, however, into the causes of the disseverance of areas, whether due to the gradual extinction of old races, or to the colonisation of new ones, remains one of the most interesting problems for solution in Geographical Botany.

OUR BOOK SHELF

Consumption, and the Breath Rebreathed. By Henry MacCormac, M.D. (London: Longmans, 1872.)

THIS work is written *con amore* by an enthusiastic physician, who has satisfied himself of the truth of the theory he advances, and is now desirous of convincing the rest of the world. The theory broached by Dr. MacCormac is that phthisis or pulmonary consumption, as well as tubercle generally, is always and exclusively the result of the breathing of air that has already been vitiated by respiration. It is well known that air that has once passed through the lungs has undergone important changes. Its oxygen is reduced in quantity, a nearly corresponding amount of carbonic acid has been added, and it also contains certain organic compounds the nature of which has not been very satisfactorily determined, but which are undoubtedly of an effete nature, and analogous in their composition to the disintegrated organic compounds eliminated from the body by the other excretory organs. The extremely deleterious action of the re-introduction into the system of the materials discharged by the intestines is now very generally known, from the inquiries that have been instituted into the nature and origin of typhoid fever; and Dr. MacCormac is perfectly justified from analogy in attributing serious results to the re-introduction into the system by the lungs of the air which has once passed through it, and which is consequently charged with decomposing substances. The carbonic acid alone is bad enough, but even if this were removed as fast as formed and replaced by oxygen, while the animal still continues to breathe the air it has already expired, there can be little doubt that it would speedily feel the effects of the other impurities with which expired air is charged. Under ordinary circumstances the only means of avoiding these effects is to permit free access of air to all and every apartment in which man is confined either by day or night; and so far we cordially endorse the views and recommendations of the author of the work before us. But when Dr. MacCormac states that tubercle is exclusively the result of breathing expired air, we think he carries his theory too far. We cannot put aside in the facile manner he adopts the influence of hereditary predisposition, nor the effects of exposure to damp and cold, when combined with insufficient food. Imperfect ventilation is so common that it is almost always as-

sociated with the other probable causes of tubercle, and it is difficult to give instances where tubercular consumption has made its appearance whilst perfectly pure air is continually breathed. But, we think, various considerations render Dr. MacCormac's views untenable. We will not refer to Iceland or to the inhabitants of the elevated plains of the Andes, or of the Steppes of Asia—all of which are sad stumbling-blocks in his way—because, as he says, they are so far off, and our facts in regard to the frequency of tubercle in these regions are perhaps not quite satisfactorily ascertained. But we may call attention to the circumstance that the disease is more common in England than in almost any other country—than in France, for example; yet, surely, the hygienic relations in regard to ventilation are superior in England to those existing on the other side of the Channel.

If air that has been breathed is so certainly the cause of tubercle, the poor population of London and other large towns should not only be decimated, but should be swept off *en masse*, for they all breathe through the night, and through a great part of the day, air so contaminated. Once more, how is it that one member of a household belonging to the upper class is attacked and dies, though all the rest, notwithstanding their being exposed to the same conditions, are preserved? Looking at animals, again, any Indian medical officer will tell Dr. MacCormac that monkeys kept in confinement, though they have never had a roof over their heads and have consequently never breathed air a second time, will die with their lungs stuffed with tubercle. Lastly, the evidence is very strong in favour of Virchow's view, that tubercular matter is originally composed of cells resembling the white corpuscles of the blood, which are either modified white corpuscles, or, as Virchow himself maintains, proceeds from the proliferation of connective tissue corpuscles. Whilst disagreeing, therefore, with Dr. MacCormac in regarding the breathing of air imperfectly freed from the products of previous respiration as the exclusive cause of tubercle, we may fully endorse his views upon the desirability of thorough and complete ventilation, especially in our sitting-rooms and sleeping apartments. The exigencies of modern civilisation seem to lead unavoidably to the close herding of mankind; but we confess it is with a sigh of regret that we see year by year long lines of close-packed houses, springing up on what were but recently green fields on every side of this great metropolis. To reach green fields and breathe fresh air is now a day's work.

H. POWER

Theory of Friction. By John H. Jellett, B.D., P.R.I.A. (Dublin: Hodges and Co.; London: Macmillan)

THIS book is, to a certain extent, of the character of a supplement to ordinary treatises on mechanics. It deals with the question of friction by the use of analytical expressions very general in the possibility of their application, on which account perhaps some of the significance of their physical character may be apt to escape the general reader, and the book is thus, perhaps, rather more suitable for advanced than for junior students.

The author brings well into prominence the radical difference between problems in statical and dynamical friction, namely, that the latter are determinate, whereas the former are not necessarily so. He says:—

"When a system of material particles, each of which rests on a rough surface, is subject to the action of external forces, it will in general be found that, of these particles, some will be in a state of motion and others in a state of rest. Everything connected with the moving particles, namely, their positions, their velocities, and the forces, geometrical and frictional, which act upon them, is fully determined by means of the dynamical and geometrical equations. The geometrical and frictional forces which act upon the quiescent particles will also be determinate, unless it be possible to form by elimination

one or more equations between the co-ordinates of the quiescent particles *only*. If this be possible, the geometrical force replacing every such equation will be indeterminate in intensity."

The character and cause of the analytical indeterminateness in the case of statical friction is enunciated in the following words, which obviously apply also to forces not frictional:—

"If any one or more of the forces acting upon the particles of a system be not determinate functions of the co-ordinates, the number of the unknown quantities will exceed the number of equations, and there will be in general an infinite number of positions satisfying the conditions of equilibrium, disposed in one or more groups, in each of which these positions succeed one another continuously."

There is an interesting chapter on the distinction between necessary and possible equilibrium, arising, so far as friction is concerned, from the fact that the coefficient of dynamical friction is less than that of statical friction, so that "if the system be disturbed from its position of equilibrium by the communication of infinitely small velocities to its several points, when the friction at each point will, of course, become dynamical, a finite force tending to augment the displacement may at once be developed at some or all of these points." The whole point of distinction between this and ordinary unstable equilibrium, when friction is not taken into account, consists in the fact of the infinitely small velocity calling into play a finite force, which it would not do in the case of ordinary unstable equilibrium, in the lapse of a finite time. Without questioning the analytical excellence and interest of the investigation, we may hesitate in adopting the change from statical to dynamical friction as a consequence of the assumption of an infinitely small velocity. We would point to the following problem (page 170) as a good example of the concrete application of the principles of the treatise:—"Two rods, AB, CD, firmly jointed together at B, rest so that A presses against a rough vertical surface, and CD lies on a rough peg in the same vertical; find the limiting positions and the nature of the equilibrium."

At the end of the book there are several problems worked out, namely, the well-known problem of a top spinning on a rough plane, the problem of "friction wheels," and one or two problems connected with the driving wheels of locomotives.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

The Adamites

I SHOULD have noticed the letter of "M. A. I.," which appeared in the last number of NATURE, with reference to my paper on "The Adamites," were it not that my silence might be interpreted as an acknowledgment of the justice of the remarks of the anonymous writer. If I had been silent, however, I trust your readers would have had more sense than to accept the dictum of a writer, anonymous or otherwise, who thinks to negative the conclusions of a paper, written at least in a truly scientific spirit, by such nonsense as the reference to *Puddy and Tuffy*. One looks for reasoning in the criticisms which appear in such a journal as NATURE, and not for a misleading statement of an opponent's position, supported by reference to general conclusions and the use of weak satire. When "M. A. I." condescends to advance an argument, I shall be happy to consider it; and if it should be unanswerable, I shall not hesitate to admit it to be so. Doubtless I ought to feel thankful for the tenderness with which he has trodden on my toes, but I have scant regard for mere courtesy where questions of science are at stake; and in the interests of truth I would rather that the errors of my

"unlucky paper" should be openly exposed, than that I should be "damned with faint praise."

Hull, April 8

C. STANILAND WAKE

The Aurora of February 4

THE Scottish Meteorological Society has just received the schedules of its observers in Iceland and Farø for February last. At Stykkisholm, on the north-west of Iceland, auroras were seen on each of the nights of the 3rd, 4th, and 5th, and at Thorshavn an aurora of a remarkably red colour was observed in the S.E. and S. in the evening of the 4th. It was also observed at North Uist, Shetland, of a very red colour, and over all the S.E. of the sky; at Monach, the most western island of the Hebrides, and at nearly all the 150 stations which report to the Society, appearing at some places as early as 5 P.M., and continuing visible at others till half-past one on the morning of the 5th. Major Stuart, the Society's observer at Janina, Greece, also reports an aurora on the 4th from 6.30 P.M. to midnight.

On the evening of the 4th much thunder and lightning occurred in Monach, South Uist, Skye, and others of the Western Isles, and on the mainland of Scotland adjacent, even as far inland as Corrimony, fifteen miles west of Loch Ness.

The weather preceding and following this aurora was very remarkable. At Stykkisholm, 22° 43' W. long., the mean height of the barometer from the 30th of January to the 5th of February was only 28.798 inches, and the wind N.E. throughout, except on one of the days, when it was E. At this same place a storm of wind, with snow showers, began at 1 A.M. of the 30th of January, and continued without intermission for 102 hours, or till 7 A.M. of the 3rd, on which day and on the 4th the weather was fine and seasonable and the wind light.

At Monach, 7° 34' W. long., a storm of wind began at 6 A.M. of January 30 and continued to blow from W.S.W., S.W., and S. till 2.30 A.M. of February 5, having thus lasted about 140 hours.

On the west of Scotland and the Western Isles, a heavy storm of wind from S. or S.W. was blowing during the evening of the 4th, the sky being generally clear, and the aurora, consequently, well seen. But at some places the sky presented a strange lurid appearance, as the aurora appeared through the opening clouds as they drifted past. Shortly after the disappearance of the aurora, the wind moderated and fine weather followed.

But in the east of Scotland the storm from the south, accompanied with drizzle and mist, did not break out till the morning of the 5th, or some time after the aurora had disappeared. It was to have been expected that an aurora extending over so much of the earth's surface would be preceded, accompanied, and followed by very different weather in different regions; and we have seen it coming thirty-six hours after a protracted period of stormy weather in Iceland, closing an equally protracted period of stormy weather in West Hebrides, and preceding a storm of wind and rain in the east of Scotland.

ALEXANDER BUCHAN

Scottish Meteorological Society, Edinburgh, April 8

HAVING seen an account of the aurora borealis which was visible in England on the night of February 4, I think that you or some of your scientific friends might like to know that a very brilliant display of aurora was visible here and in other parts of the West Indies on the same night.

On the night of February 4, I was going from Porto Rico to Puerto Plata in, roughly speaking, lat. 19° N., long. 48° W. The aurora was first seen at 8.30 P.M.; was most brilliant at 10 P.M., and gradually died away by midnight; the corresponding times at Greenwich would have been 1 A.M., 2.30 A.M., and 4.30 A.M., February 5.

I have several times seen auroras off the Western Islands, but only remember having seen one several years ago in the West Indies.

There were no pillars or points of light in this aurora, but a bright flush in the northern sky, which surged up and died away again every now and then, and was brightest about 10 P.M.

STEPHEN DIX

H.M.S. *Mersey*, St. Thomas, March 14

THE aurora of February 4 was visible at this point, but seems to have been unobserved, except by a very few. My position

was on the deck of a steamboat on the river going from this point to one 23 miles miles higher up. The aurora was first noticed by me at about 7 P.M., hanging over the woods to the north-east, and was mistaken by the Captain for a large fire, a common occurrence in our pine forests. Soon after the glow, which was a very deep red, extended to the zenith, shading off there, whilst a much fainter red light appeared in the north-west.

My last observation was made at 8.30 P.M., and the light was then still very strong in the north-east. Being then upon a train, and passing through an unbroken pine forest, I could not note the time of disappearance of the display. I saw no streamers.

There was no aurora whatever to the south at any time visible from at least sunset to 8.30 P.M. The facilities for observing the sky in that direction were peculiarly favourable from the position upon the river.

F. G. BROMBERG

Mobile, Alabama, U.S.A., March 23

On the Colour of a Hydrogen Flame

A CORRESPONDENT to your last number has troubled himself to propound an elaborate theory, to account for the blue tinge which he states is always exhibited by the flame of hydrogen. There are also several text-books on chemistry which assert that hydrogen burns with a characteristic faint blue flame. It is easy to prove, however, that the flame of pure hydrogen has no blue tinge whatever. The blueness so frequently associated with the flame of hydrogen is really due to the presence of sulphur, as is shown in a little paper I published in the *Philosophical Magazine* for November 1865.* It is possible that the facts mentioned in that paper may be turned to a practical end by some of your readers, and therefore it may not be altogether useless if I put down—for such disposal as you deem proper—one or two interesting phenomena associated with the combustion of hydrogen.

There must I imagine be some people who write text-books on experimental science without having verified any of the facts they state. Otherwise one cannot account for some obvious errors which are propagated from one writer to another. The blueness of a hydrogen flame is one such error, and another still more glaring can be traced back through several high authorities. The fact is stated that a rod of iron, or a sewing needle, remains suspended in the centre of a helix of wire through which an electric current is passing. So long as the helix is animated by the current the iron is said to behave like Mahomet's coffin, and hang in the air without the least contact with any solid body. But this is not the case, however strong the current, or small the iron, or however the helix may be disposed.

More serious errors than these are to be met with in some of the little books on science for school use, that are now cropping up like mushrooms. Heads of schools cannot exercise too much caution in the introduction of text-books on science, for they know how a poor class book once in a school is a most difficult thing to eject. It is therefore impossible to over-estimate the value of books for boys written by men like Profs. Huxley, Roscoe, and Balfour Stewart. An extraordinary impulse to scientific teaching has been given by the manuals of these and other eminent authors, and of the gladness with which such books are received by elder boys I, like others, can testify.

And now, as a teacher, permit me, Sir, to tender to the same authors not only my own gratitude, but the genuine and hearty thanks of younger boys for their simply delightful Science Primers.

W. F. BARRETT

International College, Spring Grove, W.

[We hope to give in our next number a summary of the experiments to which our correspondent alludes.—ED.]

Barometric Depressions

I HAVE only just seen Mr. Murphy's criticism on my paper, which appeared in your columns on the 21st ult. I intended that paper as a continuation of one which appeared last year. The former aimed at showing that the ordinary variations of the barometer could not be explained by aqueous vapour; the latter at proving that they were accounted for by the heating and cooling of dry air. Into this question of air *versus* vapour the earth's rotation did not enter, and I consequently took no account of it

* A year or two ago I was surprised and amused to read this investigation repeated in the pages of the *Comptes Rendus*. I forget the name of the French chemist who contributed it to the Academy, but he was doubtless unaware of anything I had written on the subject.

in my reasonings. The casual remark, however, which Mr. Murphy fastens on as involving "a serious mistake in the theory of the trade winds," was almost copied from Article 211 of "Tyndall on Heat," and as to the matter of fact, I think it is Mr. Murphy, and not Prof. Tyndall or myself, who has fallen into error. Even if I saw any reason why east and west winds should exactly balance each other on the earth's surface, I could not accept Mr. Murphy's position, that if the earth were of any other shape the trade winds could not proceed from the medial line to the extremities. He assumes that the trade winds are east winds, *independently of the shape of the earth*, whereas it is just the shape of the earth that makes them east winds. If the earth were a cylinder revolving on its axis, the trade winds (if they could arise under the circumstances) would move directly north and south, and would not be east winds at all; and I can see no reason why they should not extend to the extremity of the cylinder. See "Tyndall," *loc. cit.*

Trinity College, Dublin, April 3

Height of Cirrus Cloud

It would be interesting if any of the readers of NATURE could give some information respecting the usual height of cirrus clouds. Mr. Clement Ley, in his work, "The Laws of the Winds," states—"The time occupied by these clouds in passing from the zenith to 45°, or the contrary, furnishes us with a standard of measurement which is both convenient for simultaneous observations, and also possesses this obvious advantage, that whenever the altitude of the cloud station is at all determinable, none but the simplest of calculations is required in deducing the actual from the apparent velocity." Granted; but it would have been advantageous had he shown by an example what he means. For, he goes on to say, "The ordinary range of the actual rapidity of this current is about twice as great as that of the rapidity of the surface winds, for while the latter, at stations most fully exposed to their violence, rarely attain, in Europe, a velocity of 60 or 70 miles an hour, the most elevated clouds not uncommonly traverse a distance of 120 miles an hour, and occasionally much more." Coupling this with the next statement—"I have only once or twice observed an actually motionless cirrus cloud, and it is on rare occasions that an hour is occupied in passing from the zenith to 45°," let me ask, what would be the vertical height of such a cloud?

R. STRACHAN

Low Conductivity of Copper Wire

As one of very numerous instances which have come under his notice, Sir William Thomson desires to make known the following case of the employment of inferior copper wire in the construction of electrical apparatus. He received lately from a Glasgow bell-hanger a large quantity of cotton-covered copper wire, which was being largely used for the coils of electric bells, and upon having it tested very accurately by means of his new Multiple Arc Conductivity Box, its resistance per metre-gramme was found to be no less than 0.439 of a B. A. unit; that of ordinarily good copper wire for such purposes being about 0.16 of a B. A. unit.

J. M.

A Pelagic Floating Fish Nest

AMONG other rarities which I have been fortunate enough to procure since my arrival in the Bermudas, is a pelagic fish nest, similar in most respects to that which Agassiz has so recently described, and which was obtained by the American Expedition in the Gulf Stream in December last, while on the voyage to the West Indies. As I am very busy at present preserving and packing specimens, and the mail steamer nearly due, I have only time to send you (by way of St. Thomas) a brief description of my nest, which has been preserved in diluted alcohol. It was taken from a mass of gulf weed (*Fucus natans*) blown ashore about a month ago. This weed, by-the-by, has been especially abundant about the Bermudas during the present winter, thousands upon thousands of tons having been cast ashore by the waves during the stormy weather which has prevailed. The size of the whole mass is about eight inches by five as it hangs suspended, the former measurement being its depth. The weed is thicker at the top, and is woven together by a maze of fine elastic threads, affording a raft, from which depends the clustering mass of eggs, which I cannot illustrate better than by asking your readers to imagine two or three pounds of No. 7 shot

grouped together in bunches of several grains, and held in position by the elastic thread-work previously mentioned. These threads are amazingly strong, especially at their terminal bases on the fucus sprays, where several are apparently twisted together like the fibres of rope, and are admirably adapted to hold the mass in a position where it must always be subject, more or less, to violence, from the continued agitation of the waves in these stormy latitudes. The sea-weed is not only on the summit, but sundry sprays are interwoven with the mass of eggs, thereby rendering the fabric still more solid and secure. It is truly a wonderful specimen of Nature's handiwork; a house built without hands, resting securely on the bosom of the rolling deep.

J. MATTHEW JONES

"An Odd Fish"

SOME short time ago I observed in one of the daily papers an account of "an odd fish" which had been captured, and described by Prof. Agassiz as a denizen of the Gulf weed, on which it is said to walk with legs, and not to swim as other fishes do.

From the above account I suppose that I must have caught the fish in question in July last, during the homeward voyage of H.M.S. *Charybdis*, in lat. somewhere about 15° N., and from the Gulf weed, as described by Prof. Agassiz. The preparation I shall be happy to present to the British Museum if it should turn out to be a species of which no specimen exists in that institution.

It will be observed that the pectoral fins are developed into arms, and the ventrals into legs, though less perfect in form than are the arms.

Sir Philip Egerton has seen it, and pronounces it to be a species of blenny, a shallow water fish; and Capt. Spratt has kindly informed me that it recalls to his mind a theory entertained by the late Prof. Forbes, that the Gulf weed is the product of a shallow water, such as existed before the subsidence of the Miocene formation; and that it may contain a shallow sea fauna, although found in latitudes where the ocean is deeper.

It is a curious fact if such be the case, and one which would appear to have its counterpart in the deepest holes from which Forbes dredged molluscs, which have continued to live therein, and to have survived their congeners of former geological epochs.

J. E. MERYON

The Law of Variation

IN Mr. A. W. Bennett's notice of the sixth edition of the "Origin of Species," he calls attention to the insufficiency of the theory of "Natural Selection" to explain original variations, and says, "If it is admitted that important modifications are due to 'spontaneous variability,' &c. Now is there no cause for primary, or spontaneous variability?"

Is it not presumed under the law of inheritance that, in order that the offspring may be the *exact type* of the parent form, all the conditions of generation and life, and all the forces that affect life, whether generating or external, must be *precisely the same*? Strictly speaking, under the varying circumstances of life, this is never the case; hence slight individual variations; for no individual force can operate as a cause without its effect. These caused variations may sometimes be wide, and may be helpful or hurtful; if helpful, "Natural Selection" would take them up and preserve them and improve them. A. J. WARNER

Marietta, Ohio, March 14

Actinic Power of the Electric Light

MR. MREEZE says in NATURE of the 4th, "May not the great actinic power of the electric light be due in a great measure to the secondary waves produced by the magnitude of the disturbing force?"

This may be true, but there is a cause for the fact which is known to exist, namely, that the electric light is bluer than solar light, that it is to say, it contains a greater proportion of the shorter and more refrangible waves, which have the greatest actinic power. This is due to the absorption of more of the shorter than of the longer waves—in other words, absorption rather at the blue than at the red end of the spectrum—which takes place in the sun's atmosphere. In the magnesium light also, great actinic power is associated with a blue tint.

JOSPH JOHN MURPHY

Protective Mimicry

IN NATURE, No. 126, for 28th ult., at p. 436, M. G. Pouchet is recorded to have stated in a paper read before the Academy of Sciences, first, that prawns accommodate their colour to that of surrounding objects; second, that removing their eyes prevents this change of colour.

Of the truth of the first assertion I presume there is no doubt; but of the second I should much like to learn further, for when we speak of Protective Mimicry in all the lower forms of life, we do not assume that there is any ratiocinative mimicry. Yet if this power of protective mimicking in the prawn is dependent upon eye-sight, *i.e.*, upon the power of conveying impressions upon the optic nerve to the brain, does it not cease to be "mimicry" as generally understood, and pass into the order of mental volition? If so, how vast and interesting is the consideration!

I hope that Mr Darwin, Mr. Wallace, or some other of your scientific contributors will enlighten through your columns

March 31 IGNORAMUS

CRANIAL MEASUREMENTS

WHILE engaged in the investigation of another matter, I was induced to make a series of cranial measurements, and these I wish to record under the impression that they may be of use in the hands of some future worker, though by themselves they are not of much value.

The measurements were made at Wakefield, in Yorkshire, during 1868-9, and are those of the working-classes of the town and neighbourhood. Careful inquiry was made as to the birthplace and parentage of each subject, and no measurements are given save of those belonging to the basin of the rivers Calder and Aire. The type of the people is pre-eminently Saxon, and the results may therefore be taken as pretty accurately representing the configuration of the crania of modern Yorkshire.

Attached are also the average height and weight for each decade, and a calculation of the average cephalic index.

The measurements of the head were taken by large calipers, and are simply the greatest bi-parietal and occipito-frontal diameters, and the measurement of the face is from the tip of the chin to the root of the hair on the forehead.

The average cephalic indices of the whole would show men to be slightly more brachio-cephalic than women (by '75), while the result of the whole is decidedly eurycephalic.

The cephalic indices of each decade of age would lead us to believe that dolicho-cephalic people have a better chance of life than the brachio-cephalic people, unless we believe that the form of the cranium alters between thirty and forty years of age.

The entire table leads me to believe that there is not much value to be placed in such cranial measurements for the purposes of racial distinction; certainly not in isolated skulls; for see the curious variations of measurement in couples of the same sex taken from the same decade, as shown in the table below:—

Age.	Length of head.	Breadth of head.	Cephalic Index.	Difference in Cephalic Index.
Years.	Inches.	Inches.		
3	7.25	5.25	72.41	
3	6.25	5.30	88.00	15.59
14	7.12	5.37	75.41	
14	7.12	6.00	84.27	8.85
25	7.37	5.75	78.02	
25	6.62	5.75	86.56	8.84
32	5.87	6.12	104.26	
35	7.00	5.75	82.14	26.12
38	8.00	6.75	84.37	19.89
43	8.00	6.00	75.00	
47	7.00	7.75	110.71	35.71
52	7.25	6.00	77.43	
52	7.75	6.00	82.76	5.34
65	7.00	5.50	78.57	
69	7.12	6.25	87.78	9.21

For the purpose of contrasting the results I have obtained in the measurements of height and weight, I add a translation of Quetelet's tables:—

MEN.			WOMEN.		
Age.	Size.	Weight.	Age.	Size.	Weight.
Birth	Ft. In.	Lbs.	Birth	Ft. In.	Lbs.

LAWSON TAIT

ONE SOURCE OF SKIN DISEASES

OBSCURE affections of the skin of the face of men especially are well known to specialists to be widely spread. They are commonly classed as *eczema*, and while causing great discomfort especially at night, show nothing, or almost nothing, to the eye, if the patient be otherwise in pretty good health. Skin specialists frequently ask patients whether they have been using any new sort of soap, but no one seems hitherto to have traced any distinct communication between soap and this troublesome disease.

As I have been able pretty distinctly to do so in reference to myself, probably a brief notice of the facts may not be out of place in *NATURE*, where it is likely to be of more popular benefit than if committed to the pages of a medical journal, in which the inferences of "mere laymen" are not greatly reputed. It is a fact but very little known to the multitude of both sexes who use the "Prime Old Brown Windsor Soap" of the perfumers' shops, that by far the largest proportion of it is manufactured from "bone-grease." Few more beautiful examples of chemical transformation are to be found in the whole range of chemical manufacture than this one. At one end of a long range of buildings we find a huge shed heaped up with bones, usually such as are of little value to the bone-turner or brush-maker, in all stages of putrefaction as to the adherent or inherent portions of softer animal matter attached to them, the odour of which is insupportable.

These are crushed and ground to a coarse powder, exposed to the action of boiling water under pressure, sometimes of steam, until the grease and marrow are extracted.

We need not here pursue the subsequent treatment of the rest of the material from which bone glue and "patent isinglass" are prepared, the latter of which we often eat in the soups and jellies of the pastrycooks, and finally to the "bone dust," or phosphate of lime, nearly free from animal matter, which is produced for the use of the assayer and the china manufacturer, &c., as well as for other purposes in the arts.

But let us follow up the bone-grease, which is of a dark tarry brown colour, and of an abominable odour.

By various processes it is more or less defecated, bleached, and deodorised, and is separated into two or three different qualities, the most inferior of which goes to the formation of railway or other machinery greases, and the latter is saponified, and becomes, when well manufactured, a hard brown soap, still, however, retaining an

unpleasant smell. It is now, after being remelted, strongly perfumed, so that, like the clothes and persons of the magnates of the Middle Ages, its own evil odour is hidden by the artificial perfume.

This is the "Fine Old Brown Windsor Soap" of most of our shops. The natural brown colour of the grease gives it the right tint in the cheapest way, without the colouring by caramel, which was the original method of manufacture.

Like all other things, there are cheap and dear Windsor soaps; and for the production of the former little is done beyond saponifying and casting into blocks or bars. Were we to rely upon the many experiments that have been made as to the degree of elevation of temperature at which putrescent or other contagious matter is deprived of its moribific power, we might conclude that boiling and saponifying had made this hitherto putrescent grease innocuous.

It seems, however, more than doubtful that such is the fact in this case, for the soap thus made seems to be capable of communicating skin diseases when rubbed on the face for use in shaving.

But another promoter of irritation is not unfrequently also found. Whether it be that it is more profitable to the soapmaker to have a liberal proportion of the finer particles of the ground bone made up with the soap, or that these are difficult to separate completely, the fact is that bars of this "Brown Windsor Soap" are to be bought containing a rich mixture of those small sharp angular fragments of bone which before boiling was putrid. When a piece of such soap is rubbed hard to a man's face, the skin is more or less cut and scored by these bony particles held in the soap like emery in a head "lap," and thus the skin is placed in the most favourable state to absorb whatever there may be of irritant, or contagious, or putrid in the soap itself. The existence of the bone fragments is easily verified by solution of the soap in water or alcohol, and examination of the undissolved particles with a lens; and I can readily, if need be, send you a piece of such soap for examination.

Now, without occupying too much of your space, I may just state that I have while using such shaving soap thrice suffered from *eczema* of the face. On the first occasion I derived no benefit from treatment by the two most celebrated dermal surgeons in London, and at last the disease went away of itself after giving up shaving for a time. I had by me a quantity of this brown soap, and through inadvertence took to using it again, for a time without effect; but when dry and hot weather came, with it came a recurrence of the skin disease, which also again, after some months of discomfort, went away. Curious to make sure

whether or not the soap was the real cause, I a third time employed the soap deliberately to see if the ekzema was due to it. I was in excellent health, and in about three weeks I found the disease reestablished, so that I think the soap must be viewed as found guilty. Good white unscented curd soap is now my resource, and with no ill-effects.

Ekzema is always a distressing complaint even when affecting those in the most robust health. With those of bad constitution or lowered health, however, it seems to degenerate into bad or intractable skin diseases, so that probably this notice may not be deemed useless or uncalled for.

R. M.

THE SCHOOL OF MILITARY ENGINEERING

THERE are few educational establishments, in this country at any rate, that fulfil their object so aptly and so well, as the School of Military Engineering at Chatham. When we remember the many sciences and technical accomplishments with which the officers of the Royal Engineers are conversant, and the practical use that many of them are required to make of their acquirements, it is very obvious indeed that, to be successful, the system of education must be a most complete and substantial one. It is, in truth, necessary that a man entering either of the scientific corps of the army—the Royal Artillery or Royal Engineers—should not only be intuitively quick and clever, so as to grapple with the multifarious subjects of study, but it is moreover quite as indispensable that he should be at the outset sufficiently strong and healthy to withstand the wear and tear of so much hard work. To become a Mr. Toots would, we fear, be the fate of many young gentlemen, were they passed through the Woolwich Academy, and into these departments of the Army, without first undergoing a rigid medical examination; for the severe and lengthy curriculum is such as would certainly jeopardise the health of any but the strongest constitutions. Commissions in the Royal Artillery and Royal Engineers, be it remembered, have for many years past been obtainable only by open competition, the successful candidates being admitted into the Royal Military Academy, whence they are passed into the Army when found properly qualified. But to compete successfully for admission to the Academy in the first instance, involves already a knowledge of mathematics, of experimental and applied sciences, of languages, and other subjects too numerous to detail, such indeed as is scarcely possessed by other well-educated professional men; and this, bear in mind, is but the starting-point of the scientific soldier's education. At the Academy, where the course of special instruction sometimes continues for three years, he has to pass from a lower to an upper section, and when successfully through the examinations that beset him at every turn, he receives his commission in a provisional sort of way only. The successful Academicians highest on the list are sent to Chatham, to commence instruction in their duties as Royal Engineers, while the remainder complete their education at Woolwich and Shoeburyness, as lieutenants in the Royal Artillery. And if, after all this, there are yet dissatisfied spirits, who still exhibit a craving for more, then there is the staff college, the advanced class, instruction certificates, and other ends to be attained, enough in all conscience to satisfy the most ambitious.

It is to the School of Military Engineering that the young lieutenants of Engineers are sent for instruction in their various duties, and it is only after passing through a two years' course at this establishment that their commissions are actually secured to them. The professors, or instructors, as they are termed, are all officers of some years' standing in the corps, appointed by reason of their

intimate acquaintance with the special subjects that they teach. These subjects are not only very various, but are, moreover, always increasing, as our system of warfare continually improves. Thus, besides the subjects of surveying, construction, estimating, fortifications, telegraphy, and other more ordinary, though not less practical, matters, there have been added of late years, chemistry, photography, army signalling, torpedo service, &c., all of which the Royal Engineer must know something about.

It is evident that mere theoretical instruction in matters like these would be of little use to men who occupy such practical appointments as are filled by most Engineer officers, and it is in this respect that the School of Military Engineering may claim superiority over kindred establishments. The studies, workshops, laboratories, and demonstrating schools are of the most complete description, while the outworks and broken ground upon the Chatham lines and around the Brompton Barracks afford ample scope for the practical prosecution of those studies which require a wide field of operations. It is this practical manner of going about one's duties that is calculated above all things to impart a thorough knowledge, and to inspire officers with true confidence in their abilities. Fortifications are designed, parallels drawn, mines prepared, bridges constructed, and other siege duties executed by the students themselves, to render them conversant with their duties practically as well as theoretically, while the appointment of temporary telegraph stations, the experimental application of explosive and torpedo charges, the actual exercise of signalling, both by day and night, impart experience which could not, of course, be gained by teaching or lectures in the schools.

But it is not only the officers who benefit by the Engineering School at Chatham. The non-commissioned officers, also, are required to attend instruction in field works, and can, indeed, if they desire it, pass through the entire system of study, a course imperative on all those desirous of promotion to "foremen of works," or to other similar positions. The sappers, too, are well acquainted with at least one trade, or calling, and as every company of Engineers is made up from a due proportion of all trades, it is obvious such a complete and intelligent body of men is oftentimes invaluable. Thus it is that, in the Colonies, in Australia, New Zealand, South Africa, and other stations where detachments of Royal Engineers have been sent, their services have been found so truly valuable, every available talent being at once at hand for the carrying out of the engineering and other kindred duties necessary to be fulfilled in the occupation of a rough untravelled country. As an instance of this, we need point merely to the recent Abyssinian Campaign, which may justly be called a triumph of engineering—a gigantic piece of road-making in fact—rather than a victory over half-naked Africans; for here we have in something like six months, a rough tract of country surveyed and mapped out, four hundred miles of road made, a line of railway laid down, telegraph communication established, wells sunk, and all this over and above the transport of a large body of men and war material.

The subject of torpedoes and submarine mines was so recently discussed in these columns, that we need not again refer to any length to this latest military science just now under special investigation at Chatham. But before concluding these few remarks, we may make mention of some experiments upon an extensive scale that were not long since made with these terribly destructive machines. The charges were fired from the shore by means of electricity, the signal for their discharge being given from the distance almost of a mile; and to show the control and certainty exercisable in the system employed, there was, in one instance, a steamer made to pass harmlessly over one of the charges, which immediately afterwards, at a given signal, blew into fragments a launch following in tow.

H. B. P.

LYELL'S PRINCIPLES OF GEOLOGY

THE appearance of a new edition of the "Principles of Geology" would mark a fitting time to pass in review the state of Geologic Science, to count up what has been added to the treasury of truth, and inquire in what direction and by what methods the pioneers of Science encourage us to search for new facts. Within the limits of a short review, however, it is impossible to do more than call attention to a few of the more striking points which seem to illustrate the principles which we should apply to the examination of the phenomena of the crust of the earth.

We have before us the first edition of the "Principles of Geology," published in 1830, and that just issued in 1872. It is a remarkable fact that any work on a science which has made such rapid progress as Geology has within the last forty-two years, should, while maintaining the foremost place, have remained so little altered during that period. Almost all the passages which lay down the principles remain word for word as they were originally given to the world; the changes made from time to time being chiefly in the introduction of better illustrations or

the consideration of new questions which the progress of research has raised; but to all we find the same methods applied, and from all the same conclusions drawn as to the operation of nature in the production of the visible crust of the earth.

What, then, are the principles laid down? Thoroughly to understand this, we ought to follow our author through the interesting outline he gives of the progress of geological inquiry, in order to realise fully the opinions which prevailed when he first entered the arena. But we will only refer to the views of Hutton, which most nearly approach those of Sir Charles Lyell, who points out that "the characteristic feature of the Huttonian theory was the exclusion of all causes not supposed to belong to the present order of nature. . . . But Hutton had made no step beyond Hooke, Moro, and Raspe, in pointing out in what manner the laws now governing subterranean movements might bring about geological changes if sufficient time be allowed. He therefore required alternate periods of general disturbance and repose; and such he believed had been and would for ever be the course of nature" (1st ed. p. 63, 11th ed. p. 76).

The views which Hutton and his eloquent illustrator

FIG. 1.—DWARF'S TOWER (ZWERG-LI-THURM) NEAR VIESCH IN THE CANTON OF VALAIS.
(From a Sketch by Lady Lyell, taken September 1857.)

Playfair taught were far from meeting with general reception, and Lyell had to combat the catastrophic views of their opponents, and also to carry Hutton's uniformitarian principle further than Hutton himself allowed, and show by an appeal to observations in regions which are and have recently been in a state of volcanic activity that local catastrophic action is not inconsistent with continuity of causation. "There can be no doubt," says Sir Charles, "that periods of disturbance and repose have followed each other in succession in every region of the globe, but it may be equally true that the energy of subterranean movements has been always uniform as regards the whole earth. The force of earthquakes may for a cycle of years have been invariably confined as it is now, to large but determinate spaces, and may then have gradually shifted its position, so that another region which had for ages been at rest became in its turn the great theatre of action" (1st ed. p. 64, 11th ed. p. 77).

Our author places before us a vast array of facts collected by himself and others all over the world, which

show the ceaseless waste going on by rain, rivers, sea, frost, and ice.

The hills are shadows, and they flow
From form to form, and nothing stands.

He explains how all the land must in time be carried away and one vast ocean roll all round the world were there no compensating forces. But then he points out to us that nature does provide a compensating action in the accumulation of volcanic ash and lava thrown out during eruptions, in the upheaval of large tracts of land from below the sea, and still further, that it is part of nature's plan to shift the scene of action.

We will select a few examples from the facts adduced in proof of the gradual waste of the land.

Speaking of the effect produced by rain, our author says:—"It is not often that the effects of the denuding action of rain can be studied separately or as distinct from those of running water. There are, however, several cases in the Alps . . . where columns of indurated mud varying in height from 20ft. to 100ft, and usually capped by a single stone, have been separated by rain from the terrace of which they once formed a part, and

* "The Principles of Geology, or the Modern Changes of the Earth and its Inhabitants considered as illustrations of Geology." By Sir Charles Lyell, Bart., 11th and entirely revised edition. (London: J. Murray, 1872.)

now stand at various levels on the steep slopes bounding narrow valleys" (p. 329). "This mud, which is very hard and solid when dry, becomes traversed by vertical cracks after having been moistened by rain, and then dried by the sun. Those portions of the surface which are protected from the direct downward action of the rain by a stone or erratic block, become gradually detached and isolated." "The lower part of some of these ancient columns . . . has acquired new capping stones by the wearing out at the surface of blocks originally buried at great depths" (p. 332).

There they stand, a measure of the mass of drift that has been carried away by rain, as workmen sometimes leave a pillar of brickearth or clay here and there over a field to measure the depth of the earth they have removed.

They remind us also of the small pedestals of limestone which large boulders have sometimes preserved for themselves in the same way, and of the ice pillars where the thick stone cap had to keep off the sun instead of the rain.

By the courtesy of the publisher we are able to subjoin a sketch given by our author of an isolated stone-capped column seen by him near Viesch (Fig. 1).

In considering the action of rivers, Sir Charles notices how the clearing of forests increases the erosive power of the rain water. Speaking of a ravine in Georgia, he says,

"before the land was cleared it had no existence, but when the trees of the forest were cut down, cracks three feet deep were caused by the sun's heat in the clay, and during the rains a sudden rush of water through the principal crack deepened it at its lower extremity, from whence the excavating power worked backwards till, in the course of twenty years, a chasm measuring no less than 55 ft. in depth, 300 yards in length, and varying in width from 20 ft. to 180 ft., was the result" (p. 339).

In many parts of France the destruction of the woods has proved a source of very great injury, as they caught the rain and parted with it slowly, the roots all the while protecting the soil. But, now that the woods have been cut down, the water runs off at once, scouring away the earth from the slopes of the hills, and in the valleys causing sudden floods which sweep everything before them.

In America it is especially interesting to watch the effect produced by man in this way upon climate and water supply.

We are shown the power of rivers, especially in flood, to tear away and transport to long distances the broken masses they find in their path. The glacier and ice-sheet, too, are for ever grinding and wearing the solid rocks away. But space will not allow us to give more than one other example, and we will select the formation

FIG. 2.—GRANITE ROCKS TO THE SOUTH OF HILLSWICK NESS, SHETLAND.

of a pinnacle of solid rock by the action of the sea, which it will be interesting to compare with the column of indurated mud, of which we have given a sketch above.

In considering the waste of sea cliffs, our author quotes Dr. Hibbert's account of a passage forced by the waves through rocks of hard porphyry, where the sea tears large masses of stone from the sides and forces them along, sometimes to a distance of no less than 180 ft., and adds:—"Such devastation cannot be incessantly committed for thousands of years without dividing islands, until they become at last mere clusters of rocks, the last shreds of masses once continuous. To this state many appear to have been reduced, and innumerable fantastic forms are assumed by rocks adjoining these islands, to which the name of *Drongs* is applied, as it is to those of similar shape in 'Feroe'" (p. 512). (Fig. 2.)

By such illustrations we are taught how ceaseless and how powerful are the destroying agencies of nature. But where is all this matter transported to? Sir Charles Lyell takes us out into mid-ocean, where he points out to us the icebergs carrying their load far and wide, and dropping it here and there over the sea bottom in warmer climes. On the shingle beach we see it travelling, and in the deep blue sea, says Dr. Tyndall, we see finely-divided matter still travelling on. With our author we examine the deltas of the great rivers, the Nile, the Ganges, and the Mississippi; and he shows us that some

of the material is for a time arrested there. He tells us of the most recent discoveries in mid-Atlantic, where a chalky mud is being deposited over an area wider than that over which the ancient chalk sea has been traced; where swarms of little creatures live and die, and drop their tiny shells in such countless millions that the mud is in a great measure made up of them; where they

Sow
The dust of continents to be,

and give to us the explanation of the conditions under which that great deposit known as the Chalk was formed. Sir Charles Lyell refers to this in the following passage: "A fallacy which has helped to perpetuate the doctrine that the operations of water were on a different and grander scale in ancient times, is founded on the indefinite areas over which homogeneous deposits were supposed to extend. No modern sedimentary strata, it was said, equally identical in mineral character and fossil contents, can be traced continuously from one quarter of the globe to another. But the first propagators of these opinions were very slightly acquainted with the inconstancy in mineral composition of the ancient formations, and equally so of the wide spaces over which the same kind of sediment is now actually distributed by rivers and currents in the course of centuries. The persistency of character in the older series was exaggerated; its extreme variability in the newer was assumed without proof. In

the chapter which treats of river deltas and the dispersion of sediment by currents, and in the description of reefs of coral now growing over areas many hundred miles in length, I shall have opportunities of convincing the reader of the danger of hasty generalisations on this head. I may also mention in this place that the vast distance to which the White Chalk can be traced east and west over Europe as well as north and south, from Denmark to the Crimea, seemed to some geologists a phenomenon to which the working of the causes now in action present no parallel. But the soundings made in the Atlantic for the submarine telegraph have taught us that white mud formed of organic bodies similar to those of the ancient Chalk, is in progress over spaces still more vast" (p. 109).

The teaching of Sir Charles Lyell is that all the rocks have been formed from pre-existing rocks as far back as we can trace them, in the same manner as they are being formed now, and that those which we see preserved are such as from their nature or surrounding circumstances were fittest to survive the various denuding forces to which they would from age to age be subjected.

Surely this is the true theory of evolution applied to geology. It does not, on the one hand, hold that the world has been going on always just as it is—that after a long period, during which all the varied forces of nature have been in full activity, the earth could be found in the same state as it was at the commencement. Nor, on the other hand, does it teach that the earth has been developed according to any original tendency or impulse, but that by the *uniform* action of forces such as we see now in operation it has been *evolved* out of previous states.

Nor is the objection valid that there is any "weakness or logical defect" in the teaching which would limit the inquiry to the period of which we have a record in the crust of the earth. If the true methods are employed, it is no objection to the methods themselves that their application is not more extended.

What were the possible or necessary first combinations out of a chaotic mass is a fair subject for investigation; but an author is no more to be censured for excluding it from a work treating of the visible crust of the earth, than a philosophic writer on the history of England is to be blamed for not including in his inquiry the conditions of that part of the earth now represented by our island previous to its last emergence from below the sea.

T. MCK. HUGHES

(To be continued.)

NOTES

PROF. HUXLEY's friends will be rejoiced to hear that he has returned to this country, with his health and strength fully recruited by his absence from work; and that he has already resumed his lectures at the Government School of Mines.

THE *Examiner* prints the following extract of a letter from M. Elisée Reclus, dated Zurich, March 18:—"I am able at last to tell you that I am free. After having been kept for a long time in prisons, and sent from one prison to another, I left Paris for Pontarlier, escorted by two police agents, who left me on the free soil of Switzerland. While breathing and enjoying the pure air of liberty, I do not forget those to whom I am indebted for my freedom. Having been claimed by so many Englishmen as a student of science, I shall work on more than ever to show them my gratitude by my works and deeds."

THE Astronomer Royal will hold his first reception, as President of the Royal Society, on Saturday evening, the 27th inst.

It will be seen from our report of the Proceedings of the Chemical Society that Prof. Cannizzaro has been selected by the Council to deliver the Faraday lecture on Thursday, May 30.

THE Council of the Society of Arts has invited members of the Society to forward to the secretary, on or before April 29, the names of such men of high distinction as they may think worthy of receiving the Albert Medal, instituted to reward "distinguished merit in promoting arts, manufactures, or commerce." The recipients of the medal since its foundation, in 1864, have been Sir Rowland Hill, K.C.B., the Emperor of the French, Prof. Faraday, Sir W. Fothergill Cooke and Sir C. Wheatstone, Sir Joseph Whitworth, Baron von Liebig, M. de Lesseps, and Mr. Henry Cole, C.B.

MR. H. E. ARMSTRONG has been appointed Lecturer on Botany and Vegetable Physiology at the University of Durham College of Medicine, Newcastle-upon-Tyne.

A NUMBER of gentlemen connected with the Iron and Steel Institute, from the different parts of the Kingdom, and also from the Continent, assembled last week to the number of 200 or 300 at the Teeside Works, Middlesbrough, belonging to Messrs. Hopkins, Gilkes, and Co., to witness the first public trial of the rotary puddling machine of Mr. Danks, to which we have recently referred. The machine has been in work for two or three weeks, and realises all that has been claimed for it by its inventor, and all that has been stated of its practicability by the Iron and Steel Institute Commission, which was sent to the United States to investigate the working of the machine. On Friday the gentlemen present saw the machine charged two or three times with molten metal, and generally the heat took about an hour, with all the different preparations, from the time of drawing the heat till the introduction of another. The quantity puddled at one time was between 5 and 6 cwt. generally, but as high as 1,000lbs. have been put into the furnace at one charge. The iron, after leaving the furnace, was hammered, and then re-heated and rolled into bars, the quality of which was stated to be very superior. They were all produced from No. 4, Cleveland pig iron. The "fettling" consisted of American ore and pottery mine. The important adjunct of a "seeder," which is part of Mr. Danks's invention, is not yet built, so that the operation was not complete. An unexpected occurrence happened later in the day, an opinion having been received from counsel that Mr. Danks's patent was not valid. A meeting was held between Mr. Danks and most of the gentlemen who had entered into the provisional arrangement to pay him by the 10th of April 50,000*l.* for the right of 200 of his furnaces, to which we have already alluded, and he was informed that the arrangement would not be ratified. The question remains open, and is entrusted to a committee of the gentlemen interested, who will report to a future meeting.

THE establishment is announced of a Meteorological Observatory at the top of the mountain of Puy-de-Dôme. The original cost of 1,000*fr.* will be borne one-half by the State, one-fourth by the town of Clermont, and one-fourth by the Council-General of Puy-de-Dôme. The annual cost of its maintenance will devolve on the town of Clermont.

CAPTAIN H.R.H. THE DUKE OF EDINBURGH, K.G., has signified his intention of becoming a vice-president of the Institution of Naval Architects.

UNDER the new management and direction of the Royal Polytechnic Institution, it has been determined to re-establish the scientific department of the Institution, and Mr. Edward V. Gardner has been appointed Professor of Chemistry. We understand that the Institution is about to arrange a well-organised laboratory, proper chemical accessories for lectures, classes, analyses, &c., of which due notice will be given in the papers when the arrangements are completed.

THE Council of the Literary and Philosophical Society of Leicester have received from Mr. John Bennett the sum of 20*g.*,

for the purpose of offering prizes to students of Natural Science, and as an inducement to the useful occupation of that leisure which is afforded by shortened hours of labour. Mr. Bennett's prizes will be awarded immediately after Easter Week, 1873, according to the following plan:—1. Geology.—Three prizes will be given of the value of 3*gs.*, 2*gs.*, and 1*g.* for the best collections of the Rocks of Leicestershire, named, and with the localities given from which they were obtained. 2. Botany.—Three prizes will be given of the value of 3*gs.*, 2*gs.*, and 1*g.* for the best collections of dried specimens of the Flowering Plants of Leicestershire, properly mounted, with the name, locality, and date of gathering attached to each; and classified according to the natural system. The scientific name must be given to each plant, and the popular name or names when it has any. 3. Freshwater life, animal and vegetable.—Three prizes will be given of the value of 3*gs.*, 2*gs.*, and 1*g.* for the best aquaria, containing not more than two gallons of water, stocked with animal and vegetable life from the ponds, brooks, and rivers of Leicestershire, accompanied by a list of the specimens, with their scientific and popular names, and the locality and date of collection.

MR. JAMES CHAMBERLIN, of Norwich, announces that, with the idea of improving the breeding of pheasants, he will award ten prizes varying in value from 1*l.* to 5*l.* for the best brace raised during the present year, on conditions which may be learned on application.

It is intended to form early in May a class for the study of Botany in the field belonging to the series of Church of the Saviour Science Classes. The object of the class is to enable Science students and others to obtain a practical knowledge of Systematic Botany, and to familiarise themselves with the form, structure, and habits of the principal flowering plants of the district. As the class will be limited in number, the names of intending students should be sent at once to the teacher—Mr. Joseph W. Oliver, 35, Cannon Street; to Mr. W. T. Bulpitt, Albert Road, Aston; or to the secretary, Mr. V. H. Hemming; when arrangements will be made for a preliminary meeting.

DR. FRASER will deliver two lectures on April 19 and 26 at 8 P.M., before the Fellows of the College of Physicians, on "The connection between the chemical properties and the physiological action of active substances;" and on "The antagonism between the actions of active substances."

THE third course of Cantor Lectures of the Society of Arts for the season will be by Prof. Barff, on "Silicates, Silicides, Glass, and Glass-painting," and will be delivered on Monday evenings, from April 8 to May 13.

WE understand that at the request of the executors of the late Sir James Y. Simpson, his friend, Prof. Duns, has undertaken to write his biography.

THE *Journal of Botany* mentions the appearance of a new botanical journal, under the title of *Journal de Botanique, pure et applique*, edited by M. G. Huberson, to appear fortnightly. It will contain, besides original communications, translations, extracts, and abstracts of botanical papers presented to the Académie des Sciences.

THE Literary and Philosophical Society of Manchester has just published the tenth volume of its "Proceedings," containing an unusual number of papers of great value and interest.

WE have received a copy of the lectures delivered at the Lecture-room of the Industrial and Technological Museum, Melbourne, for the autumn session of 1871. They deal with such subjects as Geology and Palæontology in their application to useful purposes, Respiration, Radiant Energy in relation to the spectrum, Forest culture in its relation to industrial pursuits, and

various branches of manufacture. How long will it be before our Home Government undertakes such work?

A VERY useful addition has been made to the series of publications issued by order of the Secretary of State for India in Council, in the form of "A Continuation of Maps of the British Provinces in India and other Parts of Asia, 1870."

DR. STOLICZKA, the palæontologist of the Geological Survey of India, has, during his stay on deputation in Kutch, made, according to the *Times of India*, an extremely valuable collection of zoological and fossil specimens. The doctor, it is said, anticipates that fully one-half of the latter are new to science.

THE sale of Wombwell's Menagerie, to which we referred a few weeks since, took place at Edinburgh on Tuesday last. Among the prices realised were the following:—Tasmanian devil, 3*l.* 5*s.*; Diana monkey, 7*l.*; mandrill, 3*ol.*; ditto, 5*l.*; Anubis baboon, 1*ol.* 1*os.*; ditto, 8*l.* 1*os.*; condor, 15*l.*; emeu, 7*l.*; pelicans (two), 6*l.* 15*s.*; each; nyghau, 26*l.*; ditto, 1*ol.* 1*os.*; lama, 15*l.*; boomer kangaroo, 12*l.*; ocelot, 6*l.* 1*os.*; African porcupines (three), 5*l.* 1*os.* each; wombat, 7*l.*; Polar bear, 4*ol.*; brown bear, 7*l.*; performing leopard, 2*ol.*; performing leopardess, 2*ol.*; ditto, ditto, 2*ol.*; performing hyæna, 3*l.* 5*s.*; lion, "Wallace," 7½ years old, 85*l.*; royal Bengal tigress, in cub, 3 years old, 155*l.*; lion, "Duke of Edinburgh," 3 years old, 14*ol.*; lionesses, "Princess" and "Alexandra," about 3½ years old, 8*ol.* each; lioness, "Victoria," 4 years old, in cub, 1*ol.* 15*s.*; black-maned lion, "Hannibal," 6½ years old, 27*ol.*; lion, "Nero," 7½ years old, 14*ol.*; lion, "Prince Arthur," 18 months old, son of "Hannibal," 9*ol.*; lion, "Prince Alfred," 18 months old, son of "Hannibal," 9*ol.*; spotted hyæna, 15*l.*; Burchell zebra, 5*ol.*; gnu, 85*l.*; ma'e tusked elephant, 7 feet 6 inches high, nearly 8 years old, 68*ol.*, bought for the Zoological Gardens, Manchester; female elephant, 5 feet 6 inches high, 145*l.*; two boa constrictors, 6*l.* each; Malabar squirrel, 5*l.*; male Bactrian camel, 7 feet high, 12 years old, 19*l.*; female ditto, in calf, 6½ feet high, 10 years old, 3*ol.*; ditto, ditto, in calf, 6½ feet high, 5 years old, 23*l.*; male ditto, 5 feet high, 1½ years old, 14*l.*; female ditto, in calf, 5 feet high, 1½ years old, 14*l.*; male dromedary, 7½ feet high, 5 years old, 3*ol.*; female ditto, 6½ feet high, 14 years old, 21*l.*; male camel calf, born February 6, 1872, 9*l.* 1*os.*. The sale produced nearly 3,000*l.*

THE severe frost of March 21 has done an incalculable amount of damage to the fruit crop. Apples, pears, and cherries appear to have suffered most severely. It is a remarkable circumstance that although the majority of the flowers have been killed in the bud, the central part being turned perfectly black, yet the flowers expand and present externally a perfectly uninjured appearance. The *Garden* estimates the damage done to the potato crop in Jersey by the spring frosts at many thousands of pounds.

ALTHOUGH the Brighton Aquarium has been formally opened to the public, it is still in a very unfinished condition, owing to a disagreement between the proprietors and the contractor, and the severe illness of the engineer. At the time of its inauguration by Prince Arthur, on Easter Monday, but one tank was supplied with fish. When completed, the collection will by no means be confined to marine animals, a portion of the building being devoted to fresh-water tanks.

THE Senate of the University of Bombay has recently been engaged in investigating a scandal in connection with the Matriculation Examination, the passages set in Latin being taken entirely from books which one of the examiners had during the previous term made the special subject in his own class.

THE *Engineer* states that the oxyhydric light has not proved a success in Paris, and that it has been discontinued in the public lamps on the Boulevard des Italiens.

MESSRS. WATERLOW AND SONS, of 66, London Wall, announce that the invention of an entirely new method of producing a number of copies of the same manuscript without the use of ink, by a very simple process which they term printing by electricity, and to which we have already referred, may now be seen in operation on their premises.

We have received a circular from the Secretary of the Philadelphia Philosophical Association, containing a statement of its leading principles, and an outline of the method pursued in carrying them out. These principles are stated to be:—1, That force is persistent; 2, That all knowledge is relative; 3, That philosophy is the synthesis of the doctrines and methods of science; 4, The critical attitude of philosophy is not destructive, but constructive; not sceptical, but dogmatic; not negative, but positive. The Association appears to have been established in November 1871, and proposes to select a number of suitable papers, or parts of papers, for publication in a Quarterly Journal.

A CORRESPONDENT at Brighton describes a solar phenomenon visible on the afternoon of April 8, at 5.35 P.M. The sun being just within the upper part of a mass of light clouds, through which it shone with a white glare, there appeared a distinct belt of colours, in order and apparent width exactly like those of an ordinary rainbow, but apparently flattened above. Half a minute afterwards a second belt appeared, equally bright, and with no interval between the two. At the same time a fainter belt appeared to the right, but not forming a part of the same circle as the others. The three were visible together, but did not last above a minute. After the unusual appearance was first noticed, the sky above was tolerably clear, with a few light upper clouds. After the prismatic lines had faded, there was that diffused white glare round the sun which is commonly said to betoken windy weather.

THERE is now every prospect that the getting of coal by machinery will be more generally adopted than hitherto. At present it has only been adopted at a few places, but a new machine, patented by Messrs. Giltott and Copley, has just been tested at the Wharnciffe Silkstone Colliery, near Barnsley, in the presence of a number of mining engineers from various parts of the kingdom, and with most satisfactory results. In 136 minutes a bank of coal, 58 yards long and four feet eight inches thick, was cut to a depth of three feet one inch. The quantity of coal so cut would be about 80 tons in the time stated. In connection with coal machinery a hydraulic coal breaker, patented by Mr. Clubb, of London, has just been very successfully tested at the Oaks Colliery, Barnsley.

AN Indian paper prints the following interesting account of a fight between a hyæna and a man:—"About five days ago a party of six natives coming towards Deyra through the Mobun Pass, were attacked by a hyæna; it deined straight at one of them, and flew at his throat. The poor devil stretched out his hands to keep off his assailant, on which the hyæna bit them severely; his companions, instead of coming to his aid, took refuge in some adjoining trees; the man, finding himself thus deserted and his hands in a mutilated state, pluckily turned on his enemy, and seized his nose with his teeth, roaring out in the best way he could for assistance. By this means he secured the animal, and his companions, taking courage, came down from their secure position, and belaboured the beast to death with sticks. I saw the unfortunate man at the dispensary, where he had gone to have his wounds dressed, and was shown the head of his enemy having his teeth marks on the nose. I believe this is almost an unprecedented instance in the annals of natural history, as a hyæna is well known as a most cowardly brute, never venturing to attack man, but preying chiefly on dogs, carrion, and young children."

ANNUAL ADDRESS TO THE GEOLOGICAL SOCIETY OF LONDON, FEB. 16, 1872

By J. PRESTWICH, F.R.S., PRESIDENT

(Continued from page 433.)

Our Coal-measures and our Coal-supply

WHILE the presence of water has determined the early settlement of population, the existence of coal has given rise to exceptional local growths of that population, quite irrespective of the original cause of settlement. The existence of coal has created new wants, developed vast energies, enormous resources, and has established great industries dependent upon it for their maintenance and prosperity. Natural causes, unceasing and ever renewing in their action, maintain our supplies of water in a condition of constant and unflinching operation. They are physical and geological agents, equally in force in the past as in the future of the earth's history. Not so with coal, which is a store of the past, and of which we can look for no renewal. Our Coal Measures, great as they are, have defined limits, whereas our wants seem to have no bounds. With the increasing magnitude of the latter our fears of the extent of the former have increased, and have given rise to much speculation and much discussion. At first the estimates of the duration of our coal-fields were little more than guesses; but the subject has of late years been treated in a systematic manner, and in all its various bearings, in the able works of Hull, Jevons, and Warington Smyth. To obtain more precise data on these important questions, the Royal Commission of 1866 was appointed, with your President-elect, the Duke of Argyll, at its head. On the practical and economical questions different members of the Commission and separate committees have made valuable reports. I wish on this occasion merely to direct your attention to some of the more special geological bearings of the questions discussed in one of the committees, of which the lamented Sir Roderick Murchison was chairman, the object being "to inquire into the probability of finding coal under the Permian, New Red Sandstone, and other superincumbent strata."

On the evidence laid before this committee regarding England north of the Bristol coal-field, Prof. Ramsay was deputed to report, while the south of England was relegated to myself. The one district embraces all the unproved older secondary tracts between the different well-known coal-fields of the central and northern portions of England. The other district takes in that occupied by the later Secondary and the Tertiary strata, already the subject of a valuable paper in our Journal for 1856, by Mr. Godwin-Austen. The excellent mapping of our coal-districts by the Geological Survey, and their accurate sections through the several coal-fields, furnished Prof. Ramsay with data which have enabled him to prolong these sections across the intervening tracts with a degree of certainty which gives them very great value. He has presented us with 32 such sections, which, when published, will, with the text already before the public, show how great has been the task, and how successfully it has been accomplished.

The area of the exposed coal-measures of England may be estimated at about 2,840 square miles. To these Mr. Hull has added 932 square miles of coal-measures overspread by newer formations. The investigations of Prof. Ramsay lead him now to conclude that this latter total of unproved coal-measures may be increased to 2,988, to which may be added 153 miles of the Bristol coal-field, making a total of 3,141 square miles of Coal-measures under the Permian, New Red, and Triassic strata of central and northern England, or of 301 square miles more than the area of all our exposed coal-fields. This branch of the inquiry embraces curious questions of variations in the mass of the coal-measures, in the thickness of the strata, and in the number and persistence of the coal-seams. The extent and magnitude of the faults bounding so many of our coal-fields, is also a point of great difficulty, especially when it is complicated by denudations of pre-Permian and of pre-Triassic age; and in this intricate inquiry it must be borne in mind that it is only a question of superposition and faulting, but one also of removal and replacement, involving a number of important geological problems. Especially is it necessary to distinguish steep old-surface and submarine valley denudations from faults.

The other inquiry relating to the possible range of the coal-measures under the Jurassic, Cretaceous, and Tertiary strata of the south-east of England, involves questions of a much more hypothetical character, and can, in the absence of positive in-

formation, only be treated on purely abstract geological reasoning. Still it is one essentially within the range of inquiry, and the collateral geological data we possess are sufficient to guide and direct those inquiries. There are two primary points to be determined:—First, how much of the area under investigation remained dry land during the Carboniferous period, and was therefore never covered by Coal-strata. Secondly, supposing the Coal-strata to have spread over a portion of that area, how much of them escaped subsequent denudation? With regard to the first question it is comparatively easy, where the Palæozoic rocks now form the surface, to determine the antiquity of that surface, but where the old rocks are covered by great masses of other strata it becomes very difficult to determine the original conditions. Mr. Godwin-Austen has ingeniously sought to establish the position of the old coast-lines of the Carboniferous and other periods, the area of the old coal-growth, and the great features of the ancient physical geography of this period in Western Europe. I have given more especial attention to relations of the Secondary and Palæozoic formations to one another and to those points which depend upon physical conditions connected with the nature and age of old disturbances and denudations, the direction and position of the great anticlinal and synclinal lines, to the correlation of certain strata, and the dimensions of the overlying strata.

The great lines of disturbance traversing Central and North-eastern England are subsequent to the Carboniferous period, and the many detached coal-basins separated by the Penine chain and the Derbyshire hills, together with the Mountain Limestone forming those ranges, are held to be portions of one great Carboniferous formation, which, in its entirety, spread from the south of Scotland to central England, and, as we shall observe presently, probably still farther south. This great Carboniferous deposit was originally bounded on the north either by the uplands of the Scottish-border counties, or, possibly, by the Grampians; on the west by the high lands of Cumberland and Wales; while on the south we find no old exposed land-surfaces of older Palæozoic age until we reach Brittany and Central France. With respect to the deposits going on during the Carboniferous period in this area, Professor Phillips was the first to show that the lower Carboniferous series puts on, as it trends north from Derbyshire, more sedimentary conditions—that the Mountain Limestone there begins to show traces of the proximity to land, which increase rapidly in proceeding northwards,—beds of shale and sandstone and subordinate beds of coal gradually setting in in the limestone series, and increasing in importance as they approach the older border land. In the same way the approach to an old barrier-land on the south and west is supposed by Professor Ramsay to be indicated in the overlying Coal Measures by the increase in number and thickness of the beds of sandstone in the south of the Staffordshire and Shropshire coal-field, and Mr. Hull connects that old land with the Cambrian and Silurian rocks of Leicestershire.

If such were the case, the question arises, did this form a barrier which cut off the Carboniferous deposits from extending over the south of England, or was it only a partial barrier which in no way prevented the extension southward of the Carboniferous rocks?

It has been supposed that during the Carboniferous period a spur from the Silurian district of Wales extended eastward from Herefordshire into central England, dividing the coal-fields of Shropshire and Staffordshire from those of Gloucestershire; and that against this old Silurian tract the Coal Measures of South Staffordshire die out. If carried farther eastward it would limit the southern prolongation of the Coal Measures of Leicestershire, and then pass under the Oolites of Northamptonshire and the Cretaceous series of Norfolk; and so great an expansion has been given it southward, that it would equally exclude the Coal Measures from the area of the south-east of England. We have, however, no sufficient evidence of the continuous extension of these old rocks eastward of Staffordshire. Palæozoic rocks show, it is true, in Leicestershire; but there the Coal Measures wrap round them, and the older rocks seem merely to be an island in their midst. At those spots in the southern counties where they have been proved underground, I imagine they were raised by disturbances of a later date than the Coal Measures, and did not form part of the land surface of the Carboniferous period. As just mentioned, the older Carboniferous rocks show deeper-sea conditions as they trend from north to south, and the same deep-sea conditions existing in Derbyshire are found to prevail in the Mountain Limestone of Belgium, while, at the

same time, similar slight indications of distant land, in the presence of intercalated shales and imperfect coal, reappear and increase westward in their range into the district of the Boulonnais, in France. There is nothing to show but that the spur of old land stretching eastward from Herefordshire was merely a promontory ending in Warwickshire, and round which the Carboniferous sea passed and extended southward uninterruptedly to Belgium and the north of France, and westward to Somersetshire and South of Wales, spreading over all this wide area first the Mountain Limestone and then, in due order, the Coal Measures. Of the existence of these formations over the south-western and south-eastern portions of this area we have proof in Wales, Somersetshire, and Belgium. The intermediate area is covered by Jurassic, Cretaceous, and Tertiary formations, which hide from us the older rocks whose position it is our object to determine.

Just as with the disturbance which at a later period caused the Mountain Limestone of the Penine chain to break through the great expanse of Coal Measures originally spread over the central and northern counties of England, and brought up to the surface the disturbed and disjointed coal-strata, of which, after subsequent denudation, we have the isolated portions remaining in the existing coal-fields, so was the area of Southern England traversed by the earlier axis of Palæozoic rocks of the Ardennes and Mendips, bringing up the Coal Measures in like manner along their northern flanks in separate basins and troughs, some of which are uncovered by newer strata, while other basins not exposed on the surface may still possibly exist beneath the newer strata of the south-east of England. They have in fact been proved to exist under considerable portions of those newer strata of north-western France and of Belgium, and under some of the older Secondary strata in the south-west of England.

The probable continuation of this great range of Palæozoic rocks from the Rhine to South Wales, passing underground in the south of England, was shadowed out by Buckland and Conybeare in 1826, commented on by Dufresnoy and Elie de Beaumont in 1841, by M. Meugy in 1851, and more fully investigated and discussed by Mr. Godwin-Austen in 1855. These views having been controverted, the subject was fully discussed by the Commission, and again in the separate report drawn up by myself.

All geologists are agreed upon the age of this great east-and-west axis of disturbance. It took place after deposition of the Coal Measures, and before the deposition of the Permian strata. Its effects, all through its range, are singularly alike. It was not so much a great mountain-elevation, as a crumpling up and contortion of the strata for a breadth of many miles, and along a length of above eight hundred miles. The Silurian and Devonian rocks are thrown up by it into a number of narrow anticlinals, and the flanking coal-strata are tilted, turned back on themselves, squeezed and contorted in the most remarkable manner,—the same type of disturbance being apparent whether in Westphalia, Belgium, France, Somerset, or Pembroke. These great flexures have also resulted in throwing the Coal Measures into deep narrow troughs, having a length of many miles and a width of but very few.

In France, these disturbed old strata are covered transversely by Jurassic, Cretaceous, and Tertiary strata, and in Somerset by Permian, Liassic, and Jurassic strata; they sink beneath the Oolites at Frome, and reappear in Belgium from beneath the Cretaceous strata. What becomes of them in the intermediate area? It is not to be supposed that a line of disturbance of such great magnitude could have been intermittent. The coal-trough has, in fact, been followed from near Charleroi, where it passes under the Cretaceous and Tertiary strata, to Mons, Valenciennes, and Bethune, a distance of eighty-six miles. Along the whole of this line, the Chalk and overlying beds extend, with a thickness varying from 500 to 900 feet around Mons, decreasing to from 250 to 300 near Valenciennes, and increasing again towards Bethune. At Guines the Chalk was found to be 670 feet thick, and at Calais 762 feet. On the other side, the coal-trough of Somerset passes eastward under the older Secondary rocks, which in their turn pass under the Cretaceous and Tertiary strata of Wiltshire; but no attempt has been made to follow Coal Measures beyond a distance of six miles from their outcrop, where the overlying strata have been found to attain a thickness of about 450 feet.

The original supposition that the Secondary strata maintained, in the main, their regular sequence, and, to a certain extent, their thickness over large areas has long been proved to be erroneous;

but we were hardly prepared until lately to learn how rapid the variation in their thickness is. Mr. Hull has now shown that the Great and Inferior Oolites thin out from a thickness of 792 feet in Gloucestershire to 205 feet in Oxfordshire, and the Lias and Trias from 1090 feet to 400 (?) feet; while in like manner the Trias decreases from 5600 feet in Lancashire and Cheshire, to 2000 in Staffordshire, and 600 feet in Warwickshire. We also know that on the northern flank of the Mendips, the Trias, Lias, and Oolites tail off, although their dimensions in Gloucestershire are so considerable. It would appear that all the Secondary rocks, except those of the Cretaceous series, show a distinct thinning-out in their range southward, which is doubtless due to the existence of an old pre-Triassic land on the south—such as would have been formed by the prolongation of the Palaeozoic rocks of the Ardennes and Mendips through the south of England. It has been urged, on the other hand, that this thinning-out is a proof of the existence of a still older land in that area; but as the argument is based on the evidence of rocks of post-Carboniferous age, it is clear that, whether the land were of Cambrian and Silurian, or of Devonian and Carboniferous age, the result, as affecting the Secondary rocks, would be the same.

This thinning-out of the Secondary strata has now been proved not to be merely hypothetical. At three points, on or near the presumed line of the old underground range, the Tertiary and Cretaceous strata have been traversed in well-sections, and Palaeozoic rocks found to underlie them at once, without the intervention of any Triassic, Liassic, or Oolitic strata. Thus at London the presence of red and grey Sandstones, apparently of Palaeozoic age, has been proved under the Chalk at a depth of 1,114 feet. Again, at Harwich and at Calais, strata of early Carboniferous age have been found also immediately under the Chalk, at depths respectively of 1026 and 1032 feet. There is therefore reason to believe that the underground ridge of the Mendips and the Ardennes passes south from Frome through North Wiltshire, Berkshire, Middlesex, North-east Kent, and between Calais and Boulogne, at a depth beneath the Secondary strata of not more than from 1000 to 1500 feet, while the coal-troughs, which may flank this range on the north would, judging from the analogy of the structure and relations of the same rocks at Mons and Valenciennes, be met with at depths very little, if at all, greater.

To the north of this area it is probable that the thickness of the overlying rocks is greater; but we have no means of knowing exactly. In Northamptonshire the Great and Inferior Oolites and the Lias have been found not to exceed together 880 feet, at which depth the New Red Sandstone was reached; but its thickness was not proved beyond 87 feet; while at Rugby the Lias was found to be about 905 feet thick, below which 136 feet of beds of New Red Sandstone were passed through. Looking at the proved thinning out from north to south of the New Red and Permian strata, there is no reason to suppose that they would be found of any very great thickness in the southern counties. Even immediately to the south of the known coal-fields of the Midland counties, the trials for coal have not yet proved any very great thickness of these rocks. It would seem, in fact, that the extensive tracts of Chalk, Oolites, and Trias, forming the substrata of our Midland and Southern counties, constitute but a comparatively shallow crust filling up the plains and valleys of Palaeozoic rocks, the great framework of which stretches apparently at but a moderate depth under our feet, and of which the highest ridges only, such as those of the Ardennes and Mendips, now rise above ground.

It is clear, therefore, that in any search for coal, the relation of the Secondary and the Palaeozoic groups of rocks to one another being perfectly independent, the latter must be considered entirely on their own internal evidence, and apart from the bearing of the newer rocks covering them and forming the present surface, except possibly in a few cases where old lines of disturbance have proved points of least resistance, and yielded again, as suggested by Mr. Godwin-Austen, to later movements, which have equally affected the overlying formations.

It may be asked if any correlation can be established between the coal-measures of Bristol and South Wales and those of France and Belgium. So far as the identity of any particular bed of coal or of rock, it is impossible, and we should not expect it; for the variation in all the beds of any coal-basin is well known to be so great and rapid, that in the different parts of the same basin it is often difficult, and sometimes impossible, to establish any correlation; while in adjacent basins, such as those

of Wales and Bristol, or of Hainaut and Liège, such attempts have, with few exceptions, hitherto utterly failed. There are, however, more general features which serve to show, at all events, some relationship. The great dividing mass of from 2,000 to 3,000 feet of rock called Pennant exists in both the Welsh and Bristol coal-field; and the total mass of coal-measures is not very different, it being 10,000 to 11,000 feet in the one, and from 8,000 to 9,000 in the other, and there being in Wales 76, and in Somerset 55 workable seams of coal. In the Hainaut (or Mons and Charleroi) basin, the Measures are 9,400 feet thick, with 110 seams of coal; in the Liège basin 7,600 feet, with 85 seams; and in Westphalia 7,200 feet, with 117 seams. On the other hand, none of our central or northern coal-basins, with the exception of the Lancashire field, exceed half this thickness, and more generally are nearer one fourth. Further, the marked difference which exists between the northern coals and those of Wales and Somerset, the preponderance of caking-coals in the north, and of anhracite, steam, and smiths' coal in the south, equally exists between our northern coals and those of Belgium, which latter show, on the other hand, close affinities with those of Wales and Bristol. I am informed by two experienced Belgian coal-mining engineers and good geologists, who have twice visited our coal-districts, that the only coals they found like those of Belgium were the coals of South Wales and Radstock—there was the same form of cleavage, the same character of measures, and the same fitness for like economical purposes. Organic remains help us but little, but too little is yet known of their relative distribution. The plants are, as usual, the same; so also are shells of the genus *Anthracois*, and a number of small *Entomostraca*; while there is a scarcity of many of the marine forms which are more common in some of our central and northern fields. That, therefore, which best indicates the relation between the coal-fields of the south-west of England and those of the north of France and Belgium, is the similarity of mass and structure, uniformity of subjection to like physical causes, and identity of relation to the underlying older and to the overlying newer formations.

It was in the north that the conditions fitted for the formation of coal first set in. The common *Stigmaria ficoides* and various Coal Measure plants appear at the base of the Carboniferous or in the Tuedian series of Northumberland, which there overlies conformably the Upper Old Red Sandstone; and productive beds of coal exist low down in the Mountain-Limestone series. These disappear in proceeding southward, and the great productive coal-series becomes confined to beds overlying the Millstone Grit. If the coal-growth set in earlier in the north, it seems to have been prolonged farther south, under more favourable conditions, to a later period. What those conditions were—whether the proximity of a greater land-surface, of a long r and greater subsidence, with more numerous rests—we cannot yet pretend to say.

Of the prolongation of the axis of the Ardennes under the south of England there can be little doubt; nor can there be much doubt that the same great contortions of the strata, which in Belgium placed the crown of the anticlinal arch at a height of four or five miles above the level of the base of the accompanying synclinal trough, to the bottom of which the Coal Measures descend, and was the cause of similar folds in the Coal Measures of Somerset and Wales, were continued along the whole line of disturbance, and that the preservation of detached portions of the same great supplementary trough is to be looked for underground in the immediate area, just as it exists above ground in the proved area; for the minor subordinate barriers dividing the coal-basins can, I conceive, in no way permanently affect the great master disturbance, by which the presence of the Coal Measures is ruled. Whether, however, admitting that the Coal Measures were originally present, they have been removed by subsequent denudation is another question.

(To be continued.)

SCIENTIFIC SERIALS

Annalen der Chemie und Pharmacie, December 1871. A considerable part of this number is occupied by a valuable paper "On valeric acids from different sources," by Erlenmeyer and Hell. They prepared isobutyl iodide acid, and from this the corresponding iodide, which they treated with alcoholic potash to convert it into potassic valerate; the valeric acid from these reactions had no action on polarised light. They prepared valeric acid from valerian root, and this also had no rotating action on a

polarised ray. A series of experiments was made on the valeric acids obtained from active and inactive amylic alcohols, and also on the acid obtained from leucin; this latter is found to rotate a ray of polarised light to the right, but not to so great an extent as the acid which is obtained from the left-handed amylic alcohol. The acids from isobutyl cyanide, from valerian root, and from inactive amylic alcohol, show very great similarity; whilst the acids from the active alcohol and from leucin agree in most of their properties. The valeric acid made from inactive amylic alcohol is almost certainly isopropacetic acid, and that from the active alcohol is probably methacetic acid, although the authors consider that the latter acid might possibly be a molecular compound of two isomeric acids, such as isobutylic and methacetic acids. Besides this communication, there are several important physiologico-chemical papers, together with translations of two others from foreign periodicals.

THE *American Naturalist* for February commences with an exhaustive account of the Mountains of Colorado by Dr. J. W. Foster, read before the Chicago Academy of Sciences. Mr. E. L. Greene, in a short paper on the Irrigation and the Flora of the Plains, shows how a gradual alteration is going on in the character of the flora of those parts where a system of irrigation has been established, *Typha* and other marsh and water plants supplanting the original inhabitants of the drier plains. Mr. John G. Henderson, on the former range of the buffalo, brings forward evidence to show that the buffalo was at a not very remote period extremely abundant over almost the whole of the Northern United States, while he thinks that it is doomed in a short time to become extinct like the great Irish elk, the mastodon, and the dodo. The remainder of the number is occupied with reviews and short notes.

A CONSIDERABLE portion of the *Canadian Naturalist*, vol. vi., No. 2, is occupied with a report of the Edinburgh meeting of the British Association. Prof. Dawson continues his note on the Post-pliocene Geology of Canada. Prof. H. A. Nicholson (late of Edinburgh) contributes an article on the "Colonies" of M. Barrande, in which the best account we have yet seen is given of the celebrated theory of the French palæontologist. Dr. J. W. Anderson has a short article on the Whale of the St. Lawrence; Mr. S. W. Ford some notes on the Primordial Rocks in the vicinity of Troy, N.Y.; and Mr. E. S. Billings a paper on some new species of Palæozoic Fossils belonging to the classes Pteropoda and Brachiopoda.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 21.—"New Researches on the Phosphorus bases," by Dr. A. W. Hofmann, F.R.S. Ten years since the author presented to the Royal Society a series of papers on the remarkable group of phosphorus compounds first discovered by Thénard in 1847. These researches were devoted to the investigation of the tertiary and quaternary derivatives of phosphoretted hydrogen, exclusively accessible by the methods then known. Since then numerous attempts have been made to prepare the primary and secondary phosphines, but with no result until the present time. The author wishing to obtain pure phosphoretted hydrogen for lecture experiments, was led to prepare it by the action of water or soda on the beautiful compound of phosphoretted hydrogen and hydriodic acid. The ease with which this body decomposed led the author to think that it might be made available for the production of the missing compounds. For this purpose it was necessary to liberate phosphoretted hydrogen in the presence of an alcohol iodide under pressure. This could be done by heating together the phosphonium iodide and alcohol iodide in presence of some substance capable of slowly decomposing the former body, such as zinc oxide. This process yields the alcoholic phosphines, easily giving rise to the formation exclusively of primary and secondary phosphines. A further simplification of the process was tried, namely, by utilising the hydriodic acid from the phosphonium iodide in the formation of the alcohol iodide to be acted on by phosphoretted hydrogen. This was accomplished by digesting the phosphonium iodide with the alcohol; by this method it was found that only the tertiary phosphines and the quaternary phosphonium compounds already known were produced, but which were more easily and plentifully obtained by the new than by the old method. The reactions by which the various groups of phosphines are produced from phosphonium iodide are as follows, the reaction being assumed to take place in the methyl series:—

phines are produced from phosphonium iodide are as follows, the reaction being assumed to take place in the methyl series:—

Primary Phosphines

Secondary Phosphines

Tertiary Phosphines

Quaternary Phosphonium compounds

The primary and secondary methylic derivatives of phosphoretted hydrogen are prepared by placing together in a sealed tube 2 molecules of methylic iodide, 2 molecules of phosphonium iodide, and 1 of zinc oxide. The mixture is heated to 100° for six or eight hours, when the reaction is complete; on cooling the tube contains a white crystalline solid, and also a considerable amount of compressed gas. The crude product of the reaction is first treated with water, which decomposes the salts of monomethylphosphine, liberating it as a gas, which is collected in concentrated hydriodic acid; and secondly with potash, which decomposes the salts of dimethylphosphine, and liberates the dimethylated phosphine as a liquid. The whole process must be conducted in an atmosphere of hydrogen, as the two bodies are powerfully acted on by the oxygen of the air.

Methylphosphine $\text{CH}_3 \text{H}_2 \cdot \text{P}$, is a colourless and transparent gas of a most overwhelming odour, which, by cooling and by pressure, can be condensed to a colourless liquid floating on water. It boils at $-14\frac{1}{2}^\circ$ under a pressure of 0.7585 metre. At 0° it began to liquefy at 12 atmospheres pressure, and at 2½ atmospheres it was entirely liquefied. At 10° liquefaction commenced at 2½ atmospheres and was completed at 4 atmospheres pressure, and at 20° under a pressure of 4 and 4½ atmospheres. The volume weight of the gas was determined by decomposing a known weight of the iodhydrate over mercury. Experiment gave the number 24.35, the theoretical value being 24. Methylphosphine is nearly insoluble in water free from air; if it contain air the gas disappears, owing to oxidation; it is rather soluble in alcohol, more especially at low temperatures; ether dissolves but little at ordinary temperatures, but at 0° one volume of ether dissolves in less than 70 volumes of methylphosphine. When gently heated in contact with air it takes fire, as it does also in pressure of chlorine or bromine. By its union with acids it forms a remarkable series of salts, distinguished by the remarkable property of being decomposed by water.

The chlorhydrate is obtained by mixing methylphosphine with gaseous hydrochloric acid, the gases at once condense to beautiful four-sided plates; the iodhydrate $\text{CH}_3 \text{PI}$ is obtained by passing the gas into a concentrated solution of hydriodic acid; it can be crystallised in plates, which may be easily sublimed.

Dimethylphosphine $(\text{CH}_3)_2 \text{HP}$, obtained as above, is a transparent colourless liquid which is lighter than water and insoluble in it; readily soluble in alcohol and ether. Its boiling point is 25° . In contact with the air it instantly takes fire, and burns with a powerfully luminous phosphorus flame. It unites easily with acids, all its salts being exceedingly soluble. The chlorhydrate furnishes with platinum perchloride a fine crystalline salt.

Methylphosphine passed into fuming nitric acid is absorbed and oxidised, with the formation of a new acid, small quantities of phosphoric acid being also produced. The excess of nitric acid is removed by evaporation in a water bath, and the phosphoric acid by boiling with lead oxide, which forms the lead salt of a new acid which is soluble in acetic acid, and lead phosphate which is insoluble. The lead salt is decomposed by sulphuretted hydrogen, and the acetic acid removed by evaporation, which leaves the new acid as a crystalline mass resembling spermaceti, melting at 105° . Its composition is found to be $\text{CH}_3 \text{H}_2 \text{PO}_3$, and may be called methylphosphinic acid. It forms two series of salts, in which H_1 and H_2 are replaced by metals. The primary silver salt crystallises in beautiful white needles which, in contact with water, are converted into the secondary salt. The lead and barium salts of this acid have also been obtained.

Methylphosphinic acid has the same composition as methylphosphorous acid, but they are two absolutely different bodies. Methylphosphorous acid is an uncrystallisable ephemeral compound, decomposing at a gentle heat into phosphorous acid and methyl alcohol, whilst methylphosphinic acid may be distilled without decomposition.

Dimethylphosphinic acid, obtained in a nearly similar manner to the above, is a white crystalline solid, melting at 76° , and may be distilled without change. Its composition is $(\text{CH}_3)_2 \text{H PO}_2$; the silver, lead, and barium salts have been obtained, but do not crystallise so well as the salts of the last-named acid.

Phosphoretted hydrogen, on treatment with nitric acid, fixes four atoms of oxygen yielding tribasic orthophosphoric acid, whilst trimethylphosphine fixes only one atom of oxygen yielding trimethylphosphine oxide, a body which is no longer capable of forming saline compounds. We have thus a series of three bodies which may be looked on as derived from orthophosphoric acid by the replacement of hydroxyl by methyl:— $(\text{HO})_3 \text{PO}$, orthophosphoric acid; $(\text{CH}_3)_3 (\text{HO})_2 \text{PO}$, dimethylphosphinic acid; $(\text{CH}_3)_3 \text{H PO}$, dimethylphosphinic acid; $(\text{CH}_3)_3 \text{PO}$, trimethylphosphine oxide. An analogous series of bodies is known in the arsenic group.

The primary and secondary ethylic derivatives of phosphoretted hydrogen are prepared in a precisely similar manner to the methyl compounds, except that the tubes containing ethyl iodide, phosphonium iodide, and zinc oxide, must be heated to 140° – 150° for six hours.

Ethylphosphine $(\text{C}_2 \text{H}_5)_2 \text{H}_2 \text{P}$, is a transparent mobile liquid, powerfully refractive, lighter than water, and insoluble in it. It boils at 25° , and has an overwhelming odour. Its vapour bleaches like chlorine; caoutchouc placed in it becomes transparent, and loses its elasticity. It is inflamed by chlorine, bromine, and nitric acid. It is isomeric with dimethylphosphine previously described. With acids it forms salts which are crystalline and are decomposed by water.

Diethylphosphine is a colourless transparent liquid, insoluble in water and lighter than it. Its odour is very penetrating and persistent. It boils at 85° , and forms corresponding salts to dimethylphosphine which are not decomposed by water.

The primary and secondary ethyl phosphines, on oxidation by nitric acid, yield precisely corresponding products to the methylphosphines already described.

By the action of benzyl chloride, phosphonium iodide, and zinc oxide at 160° , the author has succeeded in obtaining the benzyl phosphine in a similar manner as before described.

Benzyl phosphine, $(\text{C}_6 \text{H}_5)_2 \text{H}_2 \text{P}$, is a liquid boiling at 180° , attracting oxygen with great avidity; it forms a beautifully crystalline iodhydrate, and also other salts corresponding to those obtained from methylphosphine.

Dibenzylphosphine, $(\text{C}_6 \text{H}_5)_2 \text{H}_2 \text{P}$, is a crystalline body melting at 205° , which does not oxidise in the air, nor does it form salts with acids like the corresponding dimethyl and diethylphosphines.

The author has likewise obtained the phosphorus compounds in the propyl, butyl, and amyl series, the details of which will be shortly communicated.

Geological Society, March 20—"On the Wealden as a Fluvio-lacustrine Formation, and on the relation of the so-called 'Punfield Formation' to the Wealden and Neocomian." By C. J. A. Meyer. In this paper the author questioned the correctness of assigning the Wealden beds of the south-east of England to the delta of a single river; he considered it more probable that they are a fluvio-lacustrine rather than a fluvio-marine deposit, and attributed their accumulation to the combined action of several rivers flowing into a wide but shallow lake or inland sea. The evidence adduced in favour of these views was mainly as follows:—The quiet deposition of most of the sedimentary strata, the almost total absence of shingle, the prevalence of such species of mollusca as delight in nearly quiet waters, the comparative absence of broken shells such as usually abound in tidal rivers, and the total absence of drift-wood perforated by mollusca in either the Purbeck or Wealden strata. This Wealden lacustrine area the author supposed to have originated in the slow and comparatively local subsidence of a portion of a land-surface just previously elevated. He considered that during the Purbeck and later portion of the Wealden era the waters of such lacustrine area had no direct communication with the ocean. The changes from freshwater to purely marine conditions, which are twice apparent in the Purbeck beds, and the final change from Wealden to Neocomian conditions at the close of the Wealden, were attributed to the sudden intrusion of oceanic waters into an area below sea-level. The author then pointed to the traces of terrestrial vegetation in the Lower Greensand as evidence of the continuance of river-action after the close of the Wealden period. In the concluding portion of his paper the author referred to the relation of the Punfield beds of Mr. Judd to the Neocomian and

Wealden strata of the south-east of England. From the sequence of the strata, no less than on paleontological evidence, he considered the whole of the so-called "Punfield formation" of the Isle of Purbeck to be referable to the Lower Greensand of the Atherfield section. Mr. Godwin-Austen did not agree with Mr. Judd in calling the bed at Punfield the Punfield "formation"; it was merely a bed intercalated between beds of a different character below and above. Prof. Ramsay thought that the Purbeck strata were connected with lagoons in continuity with a large river rather than with inland lakes. These, from time to time, owing to the oscillations of level, were covered with marine deposits. He did not think that the absence of gravelly deposits offered any serious difficulty in regarding the Wealden strata as marine. It seemed to him more probable, however, that the sands and clays of the Wealden were due to some ancient rivers on a large scale, and deposited at their mouths, though in some spots the beds were subject to the action of fresh and salt water alternately. He regarded the Neocomian as, to some extent, a marine representative of the Wealden, though of later date. Mr. Etheridge recalled the fact that Mr. Judd had correlated the Punfield fossils with those of the north of Spain, twenty-two species found in each being absolutely identical. He argued from this that the extent of the beds may have been far larger than might be supposed. Prof. T. Rupert Jones remarked that the Purbeck-Wealden like theory had not only been intimated by several previous writers, but had been illustrated by maps by Messrs. Godwin-Austen and Searles Wood, Jun. The Chairman, alluding to the pseudomorphs of salt mentioned by the author, stated that they had been somewhat compressed, and thus modified in form. They had also been found in other beds in the Wealden. He commented on the extension of the Wealden strata even to the south of Moscow. In the Oxford and Buckinghamshire area there was evidence of great denudation of the Purbeck and Wealden beds prior to the deposit of the Neocomian, so that great changes would seem to have taken place, giving rise to a great amount of denudation towards the close of the Wealden period. Mr. Meyer agreed with Mr. Godwin-Austen and other speakers as to there having been a certain amount of denudation of the Upper Wealden beds prior to the deposit of others upon them, but this he regarded as merely local. It was the absence of shingle rather than of gravel to which he had alluded in his paper. He thought that there was a distinction to be traced between the Neocomian of the north of England and that of the south, and that the middle beds of one were equivalent to the lower beds of the other.

Zoological Society, March 19.—John Gould, F.R.S., vice-president, in the chair. The secretary read a report on the additions that had been made to the Society's collection during the month of February 1872, amongst which were specimens of the Sumatran rhinoceros, two-wattled cassowary, and other rare animals.—Mr. R. B. Sharpe exhibited some specimens of blue rock thrushes from Europe and Eastern Asia. After tracing the different plumages through which *Petrochelidon cyanus* passed, he came to the conclusion that the Eastern blue rock thrush, *P. solitarius*, eventually becomes entirely blue like the European species, and that the birds usually called *P. mamillensis* and *P. affinis* are merely stages of plumage of *P. solitarius*.—Major Godwin-Austen exhibited a skin of *Cerionis blythii*, which had been obtained by Mr. Roberts, of the Indian Topographical Survey, in the Naga Hills.—Mr. Sclater exhibited and made remarks upon a specimen of the American yellow-billed cuckoo (*Coccyzus americanus*) which had been obtained near Buenos Ayres.—A communication was read from Prof. A. Macalister, of the University of Dublin, containing notes on a specimen of the broad-headed wombat (*Phalacrologus latifrons*).—A communication was read from Mr. W. E. Brooks, of Etawah, India, containing remarks on the Imperial eagles of India, *Aquila crassipes* and *A. bifasciata*.—A paper by Dr. J. E. Gray, F.R.S., was read, containing observations on the genus *Chelymys*, and its allies, from Australia.—Sir Victor Brooke, Bart., read a paper on *Hydropotes inermis* and its cranial characters, as compared with those of *Moschus moschiferus* and other Cervine forms.—Major Godwin-Austen read descriptions of new land and freshwater shells which he had recently met with in the Khási, North Cachar and Naga Hills of N.E. Bengal.—Mr. Howard Saunders read some notes on the introduction of *Anser albifrons* of Cassin into the European avifauna, and exhibited two examples of that species lately shot near Wexford in Ireland.

Chemical Society, March 21.—Dr. Odling, F.R.S., vice-president, in the chair.—The chairman announced that the

Faraday lecture would be delivered by Prof. Cannissaro on Thursday, May 30.—A communication from M. Maumerie, of Paris, was then read by the secretary, in which he denied the existence of the hyponitrous acid recently discovered by Dr. Divers (Proceedings of the Royal Society, xix. 425), on purely theoretical grounds, unsupported by any experiments or analyses. Dr. Divers, who was present, explained M. Maumerie's theory.—An interesting discussion took place on theoretical points connected with some remarks made by Dr. Debus, in which he stated that no organic compound existed, in which the number of atoms of hydroxyl, HO , was greater than the number of carbon atoms.

March 30.—The President delivered the annual address, in the course of which he commented upon the comparatively small number of papers communicated to the Society. The apathy and lethargy from which chemical science in this country is at present suffering, he believed to be due to a great extent to our system of university education. After the officers and council for the ensuing year had been elected, and the usual votes of thanks proposed, the meeting was adjourned.

April 4.—Dr. Frankland, F.R.S., president, in the chair.—Dr. Schorlemmer, F.R.S., delivered a very interesting lecture "On the Chemistry of the Hydro-carbons," defining organic chemistry as the chemistry of hydro-carbons and their derivatives. The characteristic properties of the paraffin, olefine, and acetylene series, and their relations one to another, were discussed, also those of the great aromatic group, the speaker pointing out the great assistance derived from the atomic theory in determining both the constitution of isomeric compounds, and also the relations existing between the various members of the aromatic series.

Entomological Society, March 18, 1872.—Mr. F. Smith, vice-president, in the chair.—R. Meldola was elected a member.—Mr. Higgins exhibited beautiful species of *Cetoniide* from Java, including some apparently new.—Mr. Bond exhibited a dimorphic example of *Acronycta leporina*, one side of which was coloured and marked as in typical examples, the other side as in the variety *bradyperina*, the two forms having at one time been considered distinct species.—Mr. Smith said that the remarks on Siberian insects at the last meeting had induced him to make a minute examination of specimens of the hornet (*Vespa crabro*) from Europe, Siberia, and North America, and he found that individuals from these districts presented no appreciable variation. The Asiatic *V. orientalis* was, however, quite distinct.—Mr. Müller read notes on *Serropalpus striatus*, which beetle he considered to be a wood-feeder, and especially attached to fir-wood; hence its occurrence in a hose-warehouse at Leicester could only be considered as accidental.—The Secretary read a long account of the ravages of locusts in South Australia in December 1871, as related in the *South Australian Register* for January 2, 1872. The insects were described as coming in swarms that darkened the air, eating every morsel of vegetation. It was found that those individuals that had partaken of leaves of the castor-oil plant were immediately killed thereby, and larkspur seemed also inimical to them.—Mr. Horne related his experiences of locusts in India. The castor-oil plant had certainly no injurious effects upon Indian species, though they were affected by the leaves of the tamarind-tree.

April 1.—Professor Westwood, president, in the chair.—Dr. A. S. Packard, Jun., of Salem, United States, was present as a visitor.—Professor Westwood exhibited a large spongy oak-gall found on the ground under an oak, which Mr. Müller considered to be the work of *Cynips radialis*. He further alluded to the differences existing in the genital apparatus of various species of the genus *Cynips*, and exhibited drawings illustrating his remarks. Also, he alluded to the different structure existing in the antennæ of various species of fleas, and maintained that these insects formed a distinct order, *Aphaniptera*. Finally he produced drawings, sent to him by a correspondent, of a minute Hymenopterous insect of the genus *Coccophagus*, parasitic upon the common *Coccus* of the orange; and he remarked that now is the best time for finding the males of *Coccus*, and especially of that infesting espalier pear trees.—Mr. Müller read notes on the larvae of *Anaspis maculata*, which he had obtained from the excrescences or outgrowths on a trunk of birch.—Mr. Butler read additional remarks on the *Pericopidae*, especially referring to species recently described by Dr. Boisduval.—Mr. McLachlan read a paper on the external sexual apparatus of the males of the genus *Acentropus*, and exhibited

drawings of this apparatus made from microscopic examination of individuals from various parts of England and the Continent. Although there were minute differences, he could find nothing to indicate, on these characters alone, that more than one species existed.

Geologists' Association, March 1.—Prof. Morris, vice-president, in the chair. "On the Geology of Hampstead, Middlesex," by Mr. Caleb Evans. The author described the deposits which had been exposed from time to time during the last few years in and near Hampstead. The principal excavations noticed were the several drainage works near Child's Hill, on Hampstead Heath, and in Frogmal Lane, and the tunnel on the Midland Railway under Haverstock Hill. It appeared from these sections that the Lower Bagshot Sand which caps the hill passes downwards into a dark sandy clay about 50 feet thick abounding with fossils, especially *Voluta nodosa* and *Pectinulus acussatus*. The *Pectinulus* bed passes down into the London Clay of ordinary character, which forms the lower part of Hampstead Hill. The author noticed the great changes in physical geography which must have taken place during the time that intervened between the deposition of the Woolwich series and that of the Lower Bagshot Sand. He considered that remains of the glacial deposits probably exist on the north side of the hill. The position of these deposits on an eroded surface of the London Clay showed the large amount of denudation that had taken place prior to the Glacial epoch. The author, in conclusion, directed attention to the existing valleys around and to the north of Hampstead, which he considered had been formed by means of the springs issuing from the water-bearing Eocene sand and the glacial gravels. Mr. A. Bell thought the leaf-beds of the Middle Eocene indicated freshwater conditions. Mr. H. Woodward considered the presence of *Zanthopsis* in these beds evidence of Marine or Estuarine origin. He pointed out the great value of the maps and sections exhibited by Mr. Evans. Prof. Morris spoke of the foreign equivalents of the London Eocene, during the deposition of which great changes of level took place. Though there are no traces of the Woolwich beds in the Belgian area, these deposits are represented near Epemay in France, while the London Clay forms a considerable area in Belgium. The patches of London clay on Salisbury Plain indicate the extension of the Lower Eocene sea over that area, and Bracklesham species are found at Chertsey. With respect to the Glacial deposits the Professor considered their importance in Middlesex very considerable, and thought it not improbable that the towns of Barnet, Hendon, and Finchley owed their origin to the presence of these deposits. The physical features of the country north of Hampstead are different from those south of that place, and this difference is due to the glacial deposits. Though the valleys of the district have been formed as we now see them by the rivers, their formation commenced during the rise of the land from the sea.—"On a recently exposed section at Battersea," by Mr. John A. Coombs. This was a brief description of a section exposed at the works of the London Gas Company now in progress near Battersea. The Thames Valley gravels are cut through and several feet of the London Clay is exposed. The gravels, which show much false bedding, yield mammalian remains, but the *Cyrena fluminis* has not been found. Several species of Mollusca have been found in the clay, but the most abundant fossil is a species of Echinodermata, the *Pentacrinus sub-basiliformis*. Mr. Huddleston noticed that at the Law Courts site in the Strand the gravels were much more ferruginous than those at Battersea, and the clay immediately underlying the gravels was altered in colour and character to a much greater depth at the former than at the latter locality.—Mr. A. Bell thought the *Cyrena fluminis* would never be found in these beds at Battersea, as it belongs he considered to beds of a different age.

Victoria Institute, February 4.—Mr. C. Brooke, F.R.S., in the chair. "Prehistoric Monotheism, considered in relation to Man as an Aboriginal Savage," being a reply to certain statements made by Sir John Lubbock in his work on Primitive Man. The paper combated the statements made by that writer, that man in his original state was a savage and without religious knowledge, from the results of investigations into the present condition of savages, from the earliest authentic records to be found in various countries, and from the writings of Aristotle, Herodotus, and others. Mr. Prichard stated that so far as his inquiries had extended, they confirmed the view taken in the paper, and the Rev. G. Percy Badger, who gave similar testimony, in alluding to an apology made by the author of the

paper, for not quoting Scripture as an authority, stated that it was perhaps judicious, as it enabled him to refute Sir John Lubbock's statement on his own ground, though it seemed strange that the latter should prefer the authority of such as Herodotus, whose writings betrayed ignorance on several points, for instance, where he refuses to believe in snow existing in a land so hot that the inhabitants were black,—to the writings of Moses, which, as writings even, were of a much higher order.

PARIS

Academy of Sciences, March 25.—M. Serret presented a note by M. A. Mannheim, containing geometrical investigations upon the contact of the third order of two surfaces.—General Morin read a memoir on the simultaneous employment of electrical induction apparatus and apparatus of deformation of solids, for the study of the laws of the movement of projectiles, and of the variation of pressures in the bore of guns.—A memoir was also read by M. V. Albenque, relating to the theory of rifled artillery, and treating of the effects of the resistance of the air upon a solid of revolution animated by a simultaneous movement of rotation.—M. Phillips presented a note by M. Bresse on the determination of brachistochrones.—A note from Father Secchi was read, giving an account of injury done at Alatri by lightning striking a lightning-conductor, and passing from it to large water pipes.—A note by M. G. Volpicelli, on the use of the proof-plane in the investigation of electrical conditions, was read.—M. Wurtz communicated a note by M. G. Salet, on the absorption spectrum of the vapour of sulphur, in which the author claimed to be the first describer of this spectrum, which was noticed by M. Gerné at the meeting of the Academy on March 18. He stated that the most perceptible dark lines coincide with the luminous bands in the spectrum of sulphur in the flame of hydrogen.—A letter from M. Donati to M. Delaunay, on auroras and their cosmoical origin, was read. The author considers these phenomena to depend on an exchange of electricity between the sun and the planets.—M. Delaunay announced the discovery at Bilk by M. Luther on the night of March 15-16 of a new planet of the eleventh magnitude. The discoverer proposes to name it *Pillho*.—The miserable dispute as to the priority of the invention of the preservation of wines by heat was continued by MM. Vergnette-Lamotte, Pasteur, and Thenard.—M. Wurtz presented a note on a new class of compounds of dulcite with the hydracids by M. Bouchardat. These compounds are crystallisable, but rather unstable.—M. Freyre presented a note by M. Prinvaux on the action of bromine upon protchloride of phosphorus, by which he has obtained some curious and unexpected compounds.—A note by M. E. Jannetaz on a new type of idioecyophanous crystals was presented by M. Delafosse.—M. C. Robin communicated a note by M. V. Féliz on the properties of the bones, in which the author stated that matters injected into the spongy tissues of the bones in the living subject are absorbed as rapidly as if they were introduced directly into the veins, from which he inferred that this spongy tissue is in direct connection with the veins, and must be regarded as forming a system of sinuses.—M. Champouillon, in a note presented by M. Larrey, stated that putrefaction is much more rapid in the dead bodies of alcoholised subjects than in those of comparatively sober individuals.—M. C. Robin presented a note by MM. Legros and Onimus containing an account of some experiments on spontaneous generation, in which the authors describe the production of fermentation within an egg penetrated with sugar by endosmotic action, and afterwards immersed in a fermenting solution of sugar.—A note by M. A. Gris containing general considerations upon the structure of the bark in the Ericinæ was communicated by M. Brongniart.—M. A. Baudrimont read a paper on the existence of mineral matter in plants, which contains some interesting results as to the amount of solid matter in fleshy plants.—M. Roulin presented a note by M. Triana on the *Gonolobus cundurango*, a South American plant, reputed to furnish a remedy for cancer.—A paper by M. L. Vaillant on the fossil Crocodiles of Saint-Gerand-le-Puy was communicated by M. Milne-Edwards. The author described three species, two belonging to the subgenus *Diplognathodon* (*D. Ratali* Pomet, and *D. gracilis* n. sp.), and a true Crocodile allied to the African species (*Croc. adumns* n. sp.)

BOOKS RECEIVED

ENGLISH.—On Bone Setting: W. P. Hood (Macmillan and Co.)—The Natural History of the Year: B. B. Woodward (S. W. Partridge.)—The Journal of Mental Science, No. 4. (Churchill).

DIARY

THURSDAY, APRIL 11.

ROYAL SOCIETY, at 8.30.—Researches on Solar Physics—Part III.: W. De La Rue, F.R.S., B. Stewart, F.R.S., and B. Loew.—The Action of Oxygen on Copper Nitrate in a State of Tension: Dr. Gladstone, F.R.S., and A. Tribe.

THURSDAY, APRIL 18, 1872

THE SECOND REPORT OF THE ROYAL COMMISSION ON SCIENTIFIC INSTRUCTION AND THE ADVANCEMENT OF SCIENCE

THE Commission has just issued its Second Report, dealing with the scientific side of the instruction given in Training Colleges and National Schools, and in the Science Classes at present conducted by the Science and Art Department. The report is so long that it is impossible to give it *in extenso*. It can, however, be easily obtained, and it should be read by all interested in one of the most important questions for England just now. Both with reference to elementary education and the Science Classes the present condition of things is fully stated, and this condition is criticised where, in the opinion of the Commissioners, criticism is necessary. The provisions of the new code we may refer to as a case in point.

The Report concludes with the following recommendations:—

SCIENTIFIC INSTRUCTION IN TRAINING COLLEGES AND ELEMENTARY DAY SCHOOLS

I. We recommend, as regards the elder children in the elementary schools, that the teaching of such rudiments of physical science as we have previously indicated should receive more substantial encouragement than is given in the regulations of the new code.

II. We recommend, as regards the younger children that Her Majesty's Inspectors should be directed to satisfy themselves that such elementary lessons are given as should prepare these children for the more advanced instruction which will follow.

III. We recommend that the mode of instruction of pupil teachers, the conditions of admission to training colleges, the duration of the course of study in them, and the syllabus of subjects taught, should be so modified as to provide for the instruction of students in the elements of physical science.

SCIENTIFIC INSTRUCTION IN SCIENCE CLASSES UNDER THE SCIENCE AND ART DEPARTMENT

IV. We recommend that the instruction in Elementary Science Classes under the Science and Art Department, be so arranged as to work in complete harmony with the general system of public elementary education, but, at the same time, we consider it important that the Education Department and the Department charged with Instruction in Science shall continue to be co-ordinate.

V. We recommend that a more efficient inspection of Elementary Science Classes be organised, and that the inspectors should advise the local committees and report on:—

- (a) The apparatus of instruction.
- (b) The state of the discipline and methods.
- (c) The general efficiency of the arrangements.

VOL. V.

VI. We recommend that teachers who have already qualified by passing the May examination in either of the advanced classes shall continue to be recognised as qualified to conduct Elementary Science Classes, with the title of Elementary Science Teacher, and to earn the grants awarded by the Department of Science and Art on the results of the examination of their scholars; but that this qualification and title shall in future only be attainable by passing in the first of the advanced classes.

VII. We recommend that should such arrangements as are hereinafter set forth for conducting the practical instruction of teachers, and for providing for them practical examination at several centres, be adopted, all elementary science teachers shall, after such practical instruction, be admissible to a further examination, which, in all suitable subjects, shall be practical. We recommend that success in this examination shall entitle a teacher to a certificate of Second Grade Science Master.

VIII. We recommend that, as an inducement to teachers to prepare for and pass this further examination, payment for results in the case of a Second Grade Science Master be made at a somewhat higher rate than in that of the Elementary Science Teacher.

IX. We recommend that an examination, both by papers and by practical tests, in any group of allied subjects defined by the Department which the candidate may select, shall be open to all those teachers who have passed in the advanced classes, or who have been otherwise admitted as Science Teachers; and that success in this examination shall entitle the candidate to receive a certificate of First Grade Science Master in that group.

X. We recommend that a greater capitation grant be payable in respect of the scholars of a First Grade Science Master teaching in any group of allied subjects with or without assistance, than in respect of the scholars of a Second Grade Science Master, provided that the Inspector report that the apparatus is sufficient, and that practical instruction has been given in each suitable subject.

XI. We recommend that, with a view of maintaining uniformity of standard in these examinations, they shall be conducted at the several local centres by the staff of Examiners acting under the Science and Art Department.

XII. We recommend that the more systematic training of the teachers of science referred to, be provided for—

- (a) By the adoption of special arrangements for this purpose in the Science School which has been referred to in our First Report; and by the recognition by the Department of similar arrangements for the instruction of this class of students in any University or College, and in Science Schools as hereinafter described.
- (b) By giving to the students of Training Colleges the opportunity of remaining a third year, during which scientific instruction may either form a principal part of the curriculum of such Colleges, or be accessible in some adjacent College or School of Science approved as efficient for that purpose.

XIII. We recommend that the Science and Art Department be at liberty to dispense with the preceding exam-

c c

nations, and to accord the privilege of First and Second Grade Science Masters in consideration of University Examinations in Science, or of a satisfactory course of study in colleges in which science is taught, as well as in other cases of obvious scientific qualification.

XIV. We recommend that in schools recognised as Science Schools, as hereinafter set forth, facilities for the employment of assistant teachers be afforded as an experiment on a limited scale, some addition being made to the emoluments of the teacher in consideration of the instruction afforded; provided the Department be satisfied, on the report of an inspector, that such assistant teacher has received practical instruction in subjects in which it is prescribed, and that he has been actively engaged in teaching.

To encourage the more advanced scholars to become assistant teachers under first grade masters in such schools, a small stipend, rising in successive years, might be granted on condition that a like sum was raised locally, subject to such conditions as the Department might deem expedient. The proportion of assistant teachers should not exceed one for every fifteen successful scholars in any science school, and no scholar should be recognised as an assistant teacher until he has passed in the first division of the elementary class in the May examination.

XV. We recommend that, with a view of training First Grade Science Teachers, exhibitions of sufficient value and in sufficient numbers be offered to elementary science teachers and to assistant teachers who have served three years, and passed in the first division of the advanced class in the May examinations; and that such exhibitions should be tenable in any University, College, or Science School recognised in Recommendation XII.

XVI. We recommend that the grants made by the Science and Art Department for buildings be extended, under sufficient guarantees, so as to embrace institutions for scientific instruction, although they may not be built under the Public Libraries Act, or be in connection with a School of Art.

XVII. We recommend that grants similar to those now made for apparatus be given for laboratory and museum fittings under proper guarantees.

XVIII. We recommend that whenever the arrangements for scientific teaching in any institution shall have attained a considerable degree of completeness and efficiency, such institution be recognised as a Science School, and be so organised as to become the centre of a group of Elementary Science Classes; and to provide the assistance of First Grade Science Masters, the loan of apparatus and specimens, and the means of instruction in the laboratories and museums to the more advanced students of the group.

XIX. We recommend that assistance be given for the formation and maintenance of such Science Schools by special grants, the conditions of which shall be determined by regulations to be framed by the Science and Art Department.

XX. We recommend that when laboratories are attached to second grade grammar schools in the schemes issued by the Endowed Schools Commissioners, the trustees of such schools be encouraged and enabled to invite the formation of elementary science classes to be taught therein.

AMERICAN WAR-OFFICE REPORTS

Report on Barracks and Hospitals, with Descriptions of Military Posts. War Department, Surgeon-General's Office, Washington, December 5, 1870; pp. 325.

Approved Plans and Specifications for Post Hospitals. Surgeon-General's Office, Washington, July 27, 1871; pp. 14.

THESE two documents are intended to fulfil for the United States army the same purpose as the Reports of the Royal Commissions of 1857 and 1863 on the sanitary state of the British and Indian armies, and the Report of the Barrack and Hospital Improvement Commission were intended to fulfil for Her Majesty's troops serving at home and abroad.

The first document contains an excellent general report by Assistant-Surgeon Billings, followed by a digest of reports from the posts of the United States army scattered all over their territory. These reports, besides dealing with the general sanitary condition and diseases of troops, are full of interesting general information regarding local topography, surface geology, hydrography, meteorology, and natural history, having reference to 151 points and districts of the country extending from the lakes to the mouths of the Mississippi, and from the east of Maine to the far west of Oregon and California. The reports are illustrated by topographical plans, showing the outlines of the more important localities, and also by plans and details of barrack and hospital arrangements.

The most common diseases to which troops are liable are malarial fevers, catarrhal affections, diarrhoea, and dysentery. Malaria appears to exist more or less in all the military "departments," while in Arizona it produces results of more importance to efficiency than this pest does in India.

The purely medical details are of more interest to professional readers, but it is evident that most of the officers who have supplied the local information have been fully alive to the importance of scientific questions generally, and hence these reports may be advantageously consulted by persons interested in the physical geography of this division of the American continent. In Mr. Billings's report the general results of these district inquiries are given, and the principles of local improvements are discussed. Those referring to post hospitals are embodied in the "approved plans and specifications," which show simple, efficient, and economical, methods of erecting hospitals of the denomination required. The plans are generally the same as those proposed by the Army Sanitary Committee in this country, but they contain one or two of those ingenious adaptations of principles for which our transatlantic cousins are famous. One of the great difficulties in American climates is to keep apartments sufficiently heated and yet to preserve the air from contamination.

In improved barracks and hospitals at home this has been effected by a peculiar form of fire grate, contrived by Captain Galton, which, while retaining the advantages of the open radiating fire, supplies the room with a large body of fresh air warmed to about 60° F., the chimney draught being used as a means of removing foul air from the room. A modification of this contrivance for burning wood is figured in the report on the Sanitary Improve-

ment of Indian Stations, drawn up by the Army Sanitary Committee.

The American contrivance produces the same result in duplicate by one fire-place intended to be fixed in the centre of the ward. There are two open fires, one facing each way. The fresh air to be warmed is passed under the floor to the space between the backs of the two fires, and is thence admitted in the room. The arrangement is simple, and ought to be effective.

It is evident from the reports generally, that much improvement is required in existing barracks and hospitals in the United States, and that overcrowding, defective ventilation, and other disease causes, still exist there as they used to do with us. It is a great step towards improvement to have an honest statement of defects. We must congratulate the Surgeon-General's department on the production of these reports, and express our hope that the executive authorities may make as good a use of them as the reporters have done of their opportunities of acquiring information regarding the stations.

OUR BOOK SHELF

Scottish Meteorology, from 1856 to 1871. Being a continued monthly and annual representation of the more important mean results for the whole country, deduced at the Royal Observatory, Edinburgh, from the schedules of observation by the Observers of the Scottish Meteorological Society, for the purposes of the Registrar-General of Births, Deaths, and Marriages in Scotland. (Edinburgh Astronomical Observations, vol. xiii.)

IN the Introduction to this work, the Astronomer Royal for Scotland tells us that it was undertaken at the request of Government, the application being to deduce from the observations taken under the auspices of the Scottish Meteorological Society, "certain monthly and general results for each and all of the stations, results supposed to be important for medical climatology and its influence on population and national welfare." The ways of statisticians are mysterious; it is difficult to understand what advantage either to medical climatology, to agriculture, or, broadly, to national welfare, is to be derived from the means here printed, means not only of barometric pressure, but of temperature, rain, and hours of sunshine, including as they do the observations at some 55 stations scattered over all Scotland, from the Shetland Islands to Dumfries, from Aberdeen to Islay—places with peculiarities of climate as distinct as could anywhere be found within anything like equal distances. We suppose, however, that there is a use for them; and, that being the case, they could not be put before the reader with more beautiful simplicity and clearness than we here find; but as we reflect on the enormous amount of skilled labour which the reductions must have cost, we cannot help regretting that meteorology can derive no advantage from it. With this report for "the purposes of the Registrar-General" is sewn up one of a very different and highly interesting character, the detailed observations of the storm which passed over the North of Scotland on October 3, 1860. These observations describe very fully a storm of extraordinary intensity, bursting almost with the suddenness of a meteor on the northern coasts; with such suddenness, indeed, that at several of the stations where the barometer was registered only at intervals of twelve hours, the whole fall, amounting, it would seem, to about 1·8 in., and the subsequent rise, passed quite unnoticed. One point which has been often, though not very closely, observed in tropical cyclones, comes out most distinctly—the remarkable rise of the barometer

beyond the limits of the storm, before and after it, in Scotland, in England, and France, about the time of its meridian passage. The lowest barometric reading anywhere observed was 28·5; this leads us to remark that, in tabulating the conclusions, the force of the wind has been unintentionally much exaggerated, owing, it appears to us, to a confusion common to all non-nautical minds between the land scale, which numbers from 0 to 6, and the Beaufort, or sea scale, which numbers from 0 to 12; for the one is not to be converted into the other by simply doubling; and the shore 6, far from being the equivalent of the Beaufort 12, is more nearly represented by 9 to 10, or at the outside by 10, which may be considered as corresponding to a velocity of about 80 miles an hour. In the discussion of the observations of this storm, many points of great interest arise: amongst others, the relationship between wind and pressure, the howling of the wind, and the ascensional motion of the air near the centre. The curt, able, cautious, and suggestive treatment of these is such as we might expect from the high standing of Prof. Smyth, and leaves little to be wished for except time for meditation.

J. K. L.

The Deviation of the Compass in Iron Ships considered practically for Sea Use, and for the Board of Trade Examinations. By W. H. Rosser. (London: Longmans.)

IN this small treatise the Deviation of the Compass in iron ships is professedly dealt with as a matter of observation, and distinct generally from magnetic science and the mathematical investigations based thereon. Mr. Rosser's long experience both as a "teacher" of officers in the mercantile marine, and an adjuster of compasses for the ships of that service, has enabled him to produce a work calculated to give those with whom he has been so long associated good practical information. The articles on the compass equipment of ships and the heeling error are judiciously given, and rightly occupy a prominent place. Whilst, however, thus commending the work, it must be regarded as meeting only a present and passing want; for from the absence of many theoretical, but not necessarily abstruse, details, the subject even as presented from a practical point of view cannot be considered as grasped with that entirety which certainly belongs to it. Those theoretical deductions which have been practically confirmed are further requisite in the advanced examinations instituted by the Board of Trade, and are, moreover, to be found in the several manuals compiled under the Admiralty and Board of Trade auspices.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

Error in Humboldt's Cosmos

I BEG to call the attention of geometers to what appears to me to be an inaccuracy in a work, which is, perhaps, the last which one would suspect to be capable of error—the "Cosmos" of Humboldt.

In vol. i. p. 293, he says, "I have found by a laborious investigation, which, from its nature, can only give a maximum limit, that the centre of gravity of the land at present above the level of the ocean is, in Europe, 630; in N. America, 702; in Asia, 1,062; and in S. America, 1,080 French feet (or 671, 748, 1,132, and 1,151 English feet) above the level of the sea." Sir John Herschel in his "Physical Geography" (Encyclop. Brit.) quotes these numbers of Humboldt as giving the height of the centre of gravity of these continents; and adds, "whence it follows, that the mean elevation of their surfaces (the doubles of these) are respectively 1,342, 1,496, 2,264, and 2,302." Herschel's conclusion is, of course, just, if Humboldt meant what he seems to say. But at the risk of being thought most presumptuous, I submit that Humboldt meant the height of the centre of gravity of the surface of the land; in other words, the mean height of

the land; and by thus misleading Sir John Herschel he has by a *coup de plume* doubled all our continents.

1. In the first volume of his "Asie Centrale," p. 165, writing on "la hauteur moyenne des continents," Humboldt says, "en cherchant à évaluer l'élevation moyenne de la hauteur des divers continents, c'est à dire la position du centre de gravité du volume des terres élevées au-dessus du niveau actuel des eaux. . . ." It thus appears that Humboldt used the words "hauteur moyenne," and "hauteur du centre de gravité du volume," as equivalent expressions, which I submit they are not. Had he said "centre de gravité de la surface," he would have been right, for that height is the mean height.

2. But though inaccurate in expression, Humboldt could never be other than right in principle. Fortunately in the "Asie Centrale" he describes with much detail the process by which he arrives at his so-called "centre de gravité du volume"; and the process legitimately leads to the mean height. He divides the continent into great areas, which I shall call $a_1, a_2, a_3, \dots$; finds the mean height of each $b_1, b_2, b_3, \dots$; by taking the mean of several; and then the mean height is

$$\frac{a_1 b_1 + a_2 b_2 + a_3 b_3 + \dots}{a_1 + a_2 + a_3 + \dots}$$

A range of mountains he regards as a triangular prism; and to find its mass he multiplies the area of the base by half the mean height, and then computes how much this would raise the whole country if spread over it; and the former number thus increased is, as is plain, the mean height.

3. Arago, in his "Astronomie Populaire," cites the labours of Humboldt with approbation, goes over all the details, adds a vast number more, and deduces numbers approximately the same for the mean height of land. Arago, it is to be observed, invariably uses the phrase "hauteur moyenne." Like Humboldt, he considers that the mean of all the continents lies between 900 and 1,000 feet.

4. Humboldt (Note 360, "Cosmos") apologises for differing from La Place, who, he says, made the mean height of continents more than three times too great. Now La Place's estimate was 3,078 feet.

I conclude, therefore, with the greatest deference, that Humboldt's "centre de gravité du volume" is an inaccurate expression, and that he meant "centre de gravité de la surface," or mean height. If this be so, Sir John Herschel has been led into the error of doubling our continents, which he estimates at a mean elevation of 1,800 feet.

It is a matter of some importance; for Sir Charles Lyell computes that the continent of N. America will be utterly washed away into the ocean by the ordinary processes of degradation in four and a half millions of years. If, indeed, this period is to be doubled, we can take a more cheerful view of the future of that continent. But I greatly fear with Sir Charles that it is limited to four and a half millions of years, unless some upheaval of the land shall protect its short span of existence. JOHN CARRECK MOORE

113, Eaton Square, March 28

Conscious Mimicry

THE idea of mimicry in animals being induced through the sense of sight appears to me to deserve more than a passing notice of M. G. Pouchet's statement that changes of colour in prawns, to accommodate them to the colour of surrounding objects, are prevented by removing the eyes of the prawns.

In 1869 I expressed my belief that such was the case, and endeavoured to embrace a large class of phenomena, as well as mimicry, within the same instrumentality. I allude to the asserted cases of the human or other fetus being affected through the sense of sight of the mother. But on ascertaining the views of many able medical men, as well as of scientific naturalists, I found opinions so divided on the matter that I did not think it desirable to pursue further inquiries, nor publish my memoranda made at the time. I could not bring myself to see that natural selection alone could produce mimicry. If it were of rare occurrence it would be called a remarkable coincidence, and might reasonably be due to selection, but what is really very general becomes a law, and must be traced to some far more "regular" influence than natural selection.

In basing the idea of mimicry in general upon the supposed act of the fetus being susceptible through the mother's sense of

sight, one is aware of the critical nature of the ground adopted, and that possibly nine-tenths of the cases recorded must be put aside as worthless; but I have strong reasons for believing the one-tenth at least to have been true.

On the other hand, the experiments of Mr. Leslie on the caterpillars of *Pontia Rapa*, which when enclosed, some in black and others in white boxes, produced chrysalises respectively modified to suit the colour of the box (*See Gossip*, 1867, p. 261), appear to support my view, as also do those of Mr. Robert Holland (*ib.* p. 279), in which the cocoons of the Emperor moth spun in white paper were white, while those on soil or in dead grass were brown.

G. HENSLOW

The Adamites

MR. C. STANILAND WAKE objects to my remarks on his paper on the "Adamites," which paper he protests is "written at least in a truly scientific spirit." This, I venture to say, is just Mr. Wake's error. He does not seem to be aware that comparative philology has a scientific method, and that words have to be compared by sound and structure according to fixed and even strict principles. Mr. Wake comes upon a Sanscrit word *pita*, father, and finds in it a primitive root *ta*, which he compares with another syllable *ta* got by cutting in two in the same way an Arabic verb, *ata*. Had he looked into the structure of Sanscrit, he would have found that *pita* is the nominative case, and precisely the one that does not show the real crude-form of the word, which is *pitar*, the *tar* being a suffix. If it is lawful to compare languages by cutting words up anyhow and finding resemblances among the bits, of course connections may be found between any languages whatsoever. In the same easy way Mr. Wake finds a relation in Polynesian mythology between a divine being called *Taata* (by the way, he should have taken the name in one of its fuller forms, such as *Tamata* or *Tangata*), and another divine being called *Tiki*. But these are two different gods with different attributes, why should their names be altered to make them into one?

Mr. Wake thinks it nonsense for me to have set up an imaginary derivation for *Paddy* and *Taffy*, as commemorating the same ancestor *Ad* or *Th*, from whom he traces *Akkad* and *Taata*. But of all ways of testing methods, one of the most useful is to try whether they can be made to prove transparent nonsense. If they can, it is evident that the method wants correction. As for my communication to you being anonymous, it was so for much the same reason that Mr. Wake's name was not mentioned in it, viz., that it is best to keep the personal element in the background in such matters, and the paper itself is the thing to be judged by.

M. A. I.

If your correspondent, "M. A. I.," instead of endeavouring to negative the conclusions of Mr. Wake's paper "by such nonsense as the reference to *Paddy* and *Taffy*," as the author of the paper justly observes, had brought forward the word *Adam* itself, and shown that, by dividing it into *Ad* and *am*, and prefixing its consonant in each case, we obtain *Dad* and *Mam*, *father* and *mother*, he might have been held to have been critical, as well as satirical.

I believe, however, that Mr. Wake is wholly wrong in his conclusions, simply because his premises are wholly wrong.

The word *Adam* has nothing of the meaning of *father* in it. The *Ad*, which Mr. Wake has so ingeniously made so much of, should for his argument be the Hebrew *Ab*, Arabic *Aba*, a *father*. To suppose that the word *Adam* has anything of the meaning of *father* in it shows a complete disregard of its root-meaning. In Hebrew the verb *adam* means *he was red or brown*, and the substantive *Adam* means *a red or a brown man*. The word *Edom* is from the same root, and means the *Red land*, probably because Red Sandstone constitutes its principal geological formation, and even *adamah*, the *ground*, is so called because of its reddish or dark brown colour. The Scripture narrative of the origin of man is that the Creator formed "the *Adam* (or man) of the dust of the *adamah* (or ground)."

If Mr. Wake's object had been to show that the *Adamites* were derived from the earth or *earth-born*, he would have found little difficulty both by internal and external evidence; he might have instanced the autochthones of the Greeks, the homines (*humus*, the ground), of the Latins, the yellow-earth men of the Chinese, and the red-clay men of the North American Indians.

April 15

B. G. JENKINS

On the Colour of a Hydrogen Flame

ACCEPTING, for the time being, the experiments of Mr. Barrett as sufficient proof that a pure hydrogen flame does not exhibit a blue colour, my "elaborate theory" must, I suppose, seek refuge under the actinic power of the electric light.

Mr. Murphy refers this actinism to the fact "that the electric light is *bluer* than solar light," the blue rays of the sun's light having been abstracted by absorption. This is a bare fact, and deals solely with the relative proportions of the different coloured rays which reach us from the two sources—it conveys no clue to the reason *why* the blue rays have an entity in the first instance.

I would not have it understood that I consider *all* the high refrangible rays to be due to secondary waves; but I think it possible that some, at least, of those emitted from sources of a very high temperature may owe their existence to this cause. Considering for the moment the electric light, we have a centre of the most intense commotion sending off waves in all directions—a condition necessary, and at the same time eminently favourable, for the production of secondary waves.

With respect to Mr. Barrett's experiments, I intend to repeat them as soon as I can command the time. The absence of the higher refrangible rays in a hydrogen flame does not, however, affect the mechanical possibility of the existence of secondary waves; although it would be reasonable to expect their presence in a pure oxy-hydrogen flame, the amplitude of the disturbed particles being necessarily very great. A. G. MEEZE

Hartley Institution, Southampton, April 15.

Another Aurora

A MAGNIFICENT aurora, scarcely inferior to that of February 4, was observed here on the evening of the 10th inst., between 8h 30^m and 9h 30^m.

The display was at its greatest beauty about 9h 0^m, when the creamy-white streamers attained an altitude of at least 60° above the N. horizon, and formed a fine contrast with a pale rose-pink background. The streamers appeared to proceed from behind a dense mass of stratus cloud which, although a moderate breeze was blowing from the S.W., remained almost stationary and unaltered during the display. The N. horizon was lighted up with a glow as intense as the early twilight on an evening in June.

With a small direct-vision spectroscope by Browning, I could see the line in the green near F, but no others. It was remarkably bright and sharply defined.

Bedford, April 12

THOS. GWYN E. ELGER

Brilliant Meteor

YESTERDAY afternoon, whilst standing on the lawn of the Observatory with my back to the sun, which was brightly shining, I saw a splendid meteor fall in the south-east. The sky at the time was of an intense blue and cloudless, with the exception of a few cirri in the north and north-west, and the meteor as seen against it presented the appearance of polished silver. The flight of the meteor was almost vertical at an altitude of about 30°, its extent was about 10°, and the trail which seemed to hang in the air and fade away like the trail of a rocket, was at the instant of explosion probably 3° in length. There was no report accompanying its disruption, or it would certainly have been heard, the neighbourhood being very still at the time.

Immediately on its disappearance I looked at my watch, it was 4h 36^m P.M. G.M.T.

Had the fall occurred after dark I have no doubt but that the meteor would have exhibited a magnificent spectacle, for its brilliancy far exceeded that of the moon as seen by daylight.

During the aurora on the evening of the 10th I observed at 9.16 P.M. a peculiar well-defined patch or short band of bright red light, the position of which, as seen from here, was N.N.E. altitude 40° to 45°. Perhaps other observers may have noticed it, and their observations will give data which may serve to assist in determining the true height of the auroral discharge.

The magnetic disturbance on the 10th commenced abruptly at 2 P.M., and was greatest during the hours of daylight, so it is extremely probable, the sky being but partially clouded, that if the aurora was visible before night, some observers may have seen it. I cannot say I have ever seen it myself in the daytime, although I have repeatedly seen cirrus clouds assuming a form very similar to auroral streamers. However, on looking at the

magnets and finding them undisturbed at the time, I have concluded that no aurora was taking place.

Kew Observatory, April 13 G. MATHUS WHIPPLE

Tide Gauges

THE subject of the tides is now one in which much interest is taken by the committee of the British Association, and it would be a great boon to many who are in a position to give attention to it, if some of your readers would supply a description of a self-registering gauge for recording the heights, which should do its work effectively and not very expensively. Many plans are suggested; the difficulty is to know which is the best.

Vicarage, Fleetwood, April 11

JAMES PEARSON

NOTES ON THE RAINFALL OF 1871

THE following are a few particulars of the rainfall of the past year, deduced from daily observations with Glaisher's (Hall's improved) rain gauge* at Fulwell,† near Twickenham, Middlesex, the place of observation being in lat. 51° 26' 0" N. long. 0° 20' 53" W.

The orifice, or receiving surface of the gauge, which is placed horizontally, is 8.00 inches in diameter (50.26 in area), the height of the same above the ground being one foot, and, as determined by spirit levelling from Ordnance B.M., 47 feet above mean sea-level.

The results of the observations have been calculated in the imperial system, and metric equivalents are placed in brackets, the use of which (brackets), for the sake of distinction, has been avoided in all other formulæ; they have, in each instance, been calculated to two or three places of decimals, but are here given, so far as is practicable, in whole numbers; the nearest integer, in each instance, having been taken; they have further been calculated upon the hypothesis that the rainfall was equally distributed.

In the following table:—

α = depth of rainfall in inches } Total fall
 β = depth in centimetres } per month.
 γ = number of gallons } Equivalents
 δ = number of hectolitres } per acre.

	α	β	γ	δ
January	2.03	5.156	45,675	2,074
February	1.00	2.540	22,500	1,022
March	1.08	2.743	24,300	1,103

December	1.19	3.023	26,775	1,216

The total depth during the year was 22.42 in., or 56.947 centimetres.

The rainfall on a square mile during the year was $22,500 \times 640 \times 22.42 = 322,848,000$ gallons ($\div 22.024 = 14,658,918$ hectolitres), or $640 \times 4840 \times 9 \times 22.42 \div 12 = 52,056,144$ cubic feet ($\div 35.31658 = 1,474,835$ cubic metres).

A cubic inch of distilled water at a temperature of 62° Fahr. (16.66 C.) is a standard of weight; this quantity has been determined to weigh 252.458 grains, of which 437.5 make one ounce Av.‡ therefore, a cubic foot weighs

* Vide *Scientific Opinion*, Vol. iii., pp. 429, 440 (May 18, 1870).

† Although the observations refer especially to this locality, they will probably be scarcely the less interesting.

‡ *Practical Meteorology*, by John Drew, Ph.D., sec. 127, p. 290.

$252'458 \times 1728 = 997'137$ oz. Av.; hence we may assume that the entire weight of water which fell on one square mile was $\frac{52,086,144 \times 997'137}{35,840} = 1,449,136$ tons,

($\approx 984 = 1,472,699$ milliers). Some idea of this enormous quantity will be afforded by the following illustrations.

The Thames at London Bridge is, at low water, nearly 700 feet wide,* and from 12 to 13 (say 12'5) feet deep. We will, for the sake of argument, assume the sectional area throughout to be $700 \times 12'5 = 8,750$ square feet. The amount of rainfall on a square mile was equivalent to a volume of water corresponding in sectional area to

the Thames at London Bridge, and extending $\frac{52,086,144}{8,750 \times 5280} = 1'127$ miles in length; in other words, it would extend from London Bridge, past Cannon Street (Railway), Southwark and Blackfriars (Railway and Road) Bridges, to about Somerset House, or nearly to Waterloo Bridge.

The same quantity of water would equal the contents of a river or canal having an uniform width of 20 feet, and depth of 5 feet—the sectional area being 100 feet—extending nearly 99 miles, or 159 kilometres in length.

The cubic contents of a sphere are $\frac{2}{3}$ of that of a cylinder of the same diameter and altitude. But the altitude being equal to the diameter, and $\frac{2}{3}$ of 7854 being 5236, the contents may be expressed as I have arranged it in the following formula. Calling Δ the diameter, and x the cubic contents required, we have

$$\Delta^3 \times '5236 = x,$$

or the reverse, calling C the cubic contents and x the diameter required.

$$\sqrt[3]{\frac{x}{'5236}} = x.$$

By these formulæ I have determined that the rainfall on a square mile—under the conditions mentioned in paragraph 3—was equivalent to a globe of water 463 ft. in diameter (approximate), a height exceeding that of the top of the cross surmounting the dome above the pavement of the churchyard of St. Paul's Cathedral (370 ft.†) by 93 ft.

The same quantity of water was equivalent to the following:—

A circular column of water 144 ft. in diameter (corresponding to that of the dome of St. Paul's Cathedral—interior surface‡), rising to a height of 3,198 ft.; in other words, it would be upwards of 8½ times the height of the cross before-mentioned.

Or, with regard to specific gravity:—

A circular column of lead (cast)§ of the same diameter (144 ft.—a cubic foot being taken as 710 lbs., or 11,360 oz.) containing 4,571,921 cubic ft., and rising to a height of 278 ft.

A circular column of granite (Aberdeen) of the same diameter, a cubic foot being taken as 2,690 oz.¶, containing 19,307,443 cubic feet, and rising to a height of 1,184 ft.

But perhaps the most remarkable illustration will be afforded by comparing the weight of this quantity of water to a corresponding weight contained in, say, a number of railway coal waggons. Railway coal waggons are constructed to carry, on an average, from eight to ten tons. Let us assume it as the former of the two, and the average length of a number of waggons as 16 feet

each from buffer to buffer. It would require no less than 181,142 such waggons to carry a corresponding weight of coal (or 3,623 heavy trains of fifty waggons each) which would, when close coupled, *i.e.*, buffer to buffer, extend over a distance of nearly 549 miles (883 kilometres) represented very nearly by the distance from London (Euston Station) to Aberdeen *via* Rugby, Stafford, Crewe, Carlisle, Glasgow, and Perth (London and North Western and Caledonian Railways). An express train, travelling at an uniform speed of sixty miles per hour, would take upwards of nine hours to run this distance, in other words, to pass this number of waggons; or, if I may indulge in another illustration, this number of waggons would, if travelling at an uniform rate of twenty-five miles per hour—which is about the average rate of goods trains—be nearly twenty-two hours in passing any given point, such, for instance, as a station. (Aberdeen is upwards of 130 miles N.N.E. of Edinburgh by the Caledonian Railway—Eastern route from London.)

Such a means of illustration as the one I have here set forth may not be considered in all respects strictly scientific; it has nevertheless this advantage, it enables us to comprehend something of the truth and magnitude of the subject—although dealing with hypotheses—where mere abstract figures would fail to produce anything like a similar result.

JOHN JAMES HALL

ON CERTAIN PHENOMENA ASSOCIATED WITH A HYDROGEN FLAME

PHENOMENA of much interest and possibly of future usefulness are associated with the combustion of ordinary hydrogen.

I. To study these phenomena free from disturbing causes three things should be attended to, although the effects to be described can be obtained without any special precaution.

(a) The gas must be stored and purified in the ordinary way, namely, by passing into a gas-holder through a solution of potash, and then through a solution of perchloride of mercury or nitrate of silver.

(b) From the holder the gas must be led through red or black india-rubber tubing to a platinum, or better, a steatite jet.

(c) And then the gas should be burnt in a perfectly dark room, and amid calm and dustless air.

II. In this way the flame gives a faint reddish brown colour, invisible in bright daylight. Issuing from a narrow jet in a dark room, a stream of luminosity, more than six times the length of the flame, is seen to stretch upward from the burning hydrogen. This weird appearance is probably caused by the swifter flow of the particles of gas in the centre of the tube. The central particles as they shoot upward are protected awhile by their neighbours; metaphorically, they are hindered from entering the fiery ordeal which dooms them finally to a watery grave. Dr. Tyndall has shown that the radiation from burning hydrogen is hugely ultra-red, and moreover, that it has not the quality of the radiation from an elementary body like hydrogen, but practically is found to be the radiation from molecules of incandescent steam. So that, except at its base, a hydrogen flame is a hollow stream of glowing water raised to a prodigious heat.

III. Bringing the flame into contact with solid bodies, in many cases phosphorescent effects are produced. Thus allowing the flame to play for a moment on sand paper and then promptly extinguishing the gas, a vivid green, phosphorescence remains for some seconds. The appearance is a beautiful one, as a luminous and perfect section of the hollow flame is depicted. Similar phosphorescence is produced by the flame on white writing paper,

* I quote this from a paper "On the Rainfall of Devonshire," by W. Pengelly, Esq., F.R.S., *Scientific Opinion*, Vol. i. p. 137. (From the Transactions of the Devonshire Association for the Advancement of Science, 1863.) The depth is confirmed in the *Encyclopædia Britannica*, Vol. xxi. p. 163.

† *Encyclopædia Britannica*, vol. xiii. p. 670.

¶ Ibid.

or on marble, or chalk, or granite, or gypsum, &c. But no such effect is produced by coal gas, or olefiant or marsh gas. It is evidently a question of temperature, as oxygen given through coal gas shows the phosphorescence well.

IV. Far exceeding in generality the effect just noticed is a really magnificent *blue image of the flame* that starts up on almost every substance with which the flame is brought into contact. I have already drawn attention to this effect in the Phil. Mag. for November 1865, and in my letter of last week pointed out how the same effect has more recently formed the subject of a memoir, presented through M. Wurtz to the Paris Academy of Sciences, the author of that paper evidently being unaware that the subject had already been investigated by myself.

The appearance is as follows: When the hydrogen flame is brought either vertically or sideways, say, upon a white plate or a block of marble, there instantly appears a deep blue and glowing impression of the exact size and shape of the hollow flame. The moment the gas is extinguished, or the flame removed to the slightest distance from the solid, the effect as instantly ceases. If the flame be brought successively to the same spot on the solid, the effect grows fainter and finally vanishes, but instantly reappears upon an adjoining portion.

Other combustible gases, such as carbonic oxide, or marsh gas, or olefiant, or coal gas, do not yield this effect, nor does any lamp flame, luminous or otherwise; nor is it obtained in the oxidising flame of an ordinary blow-pipe; but it is imperfectly produced in the reducing flame when coal gas is used; it is not seen when oxygen is driven through coal gas, unless the latter be in excess, and it is poorer and vanishes more quickly with the oxyhydrogen flame than with hydrogen alone. This blue luminosity is, therefore, not a question of heat, but some property depending either on (a) the chemical nature of hydrogen, or on (b) the physical effect of its radiation. At first I thought it was the latter, and that it was a new form of fluorescence, so closely did it resemble those phenomena. But after a week's incessant experimenting, the true cause was hunted down, and found to be dependent on the former effect (a), and in every case ultimately due to the presence of *sulphur*. A chemically clean body, or a freshly broken surface, did not show the blue coloration; but after exposure for a short time to the air of London, the substance invariably yielded the blueness; this, however, was not the case when the clean surface was covered by a shade, or exposed to the air of the open country. The combustion of coal gas and coal fires yields sulphate of ammonia, a body often deposited in acicular crystals in the glass tubes in a laboratory. Sulphate of ammonia is decomposed by a hydrogen flame, and when that salt is brought into contact with burning hydrogen, it permanently yields the blue coloration. Hence this body is probably the main source of the blueness seen whenever a hydrogen flame comes into contact with glass tubes or a dirty surface. This effect must repeatedly have been seen by every one who has experimented on singing flames.

When the blueness, as is so often the case, is seen tinged the flame itself, without contact with any body, the sulphur is derived either from the vulcanised tubing, the dust of which is taken up by the passing gas; or if the hydrogen be burnt from the bottle generating it, the blueness is due to the decomposition of the sulphuric acid spray, as will be shown further on.

As a chemical re-agent for detecting sulphur, the delicacy of a hydrogen flame is extraordinary. This fact was estimated as follows:—Pure precipitated silica yields no blueness with the flame; 500 grains of silica were intimately mingled with one grain of milk of sulphur. Less than a $\frac{1}{100}$ th of a grain of this mixture was thrown on the surface of pure water or placed upon chemically clean platinum foil. The water is best, but in either case the

blue colour (absent before) now shot forth on bringing the hydrogen flame down. Tried again and again with fresh portions, the effect was very evident, but quickly vanished. The sulphur in a similar portion of the mixture could not be detected chemically by nitro-prusside of sodium. The wonderful sensitiveness of the flame may be still better seen in another way. Immediately after washing, the fingers show no colour when brought for a moment into the flame, but if a white india-rubber tube be touched ever so lightly, the fingers not only show a vivid blueness, but for some time any clean object touched by them, such as platinum foil, shows traces of sulphur by the appearance of the blue coloration with the flame. A block of melting ice continually weeps itself free from dust, and thus presents an excellent surface upon which to try the foregoing experiment. Or a plate of platinum, after heating to redness, may be written over with a stick of sulphur. If kept covered, the invisible letters may long after be traced out by sweeping the hydrogen flame over the surface of the platinum.

Examined through a prism, the blueness derived from any source shows blue and green bands, similar to the spectrum of sulphur, but I have noticed also a red band. This mode of obtaining a sulphur spectrum suggests further inquiry. White marble smeared over with a bit of sulphur, or with vulcanised rubber tubing, is a convenient source for obtaining the effect at pleasure.

Some sulphates and sulphides show the blueness with the flame, and are evidently decomposed by the hydrogen. Thus sulphate of soda gives no blue appearance, whilst sulphate of ammonia, or alum, does.

V. Various liquids were tried in contact with the flame. Sulphuric acid was very notable. Here a magnificent blue effect was observed. For persistence and brilliancy of the colour, this experiment leaves nothing to be desired; the spectrum is very fine. If the liquid is in a glass dish when the flame is brought vertically down, the blueness lights up the glass in a lovely manner.*

VI. But the presence of sulphur is by no means the only body that a hydrogen flame reveals. The least trace of *phosphorus* is detected by the production of a vivid green light. It is striking to notice the wonderful subdivision of matter in these experiments, and how an immeasurable trace of an element can evoke pronounced and apparently disproportionate effects.

Might not this ready detection of minute quantities of sulphur and phosphorus be of use in the manufacture of iron; and might not hydrogen introduced into the molten metal be employed for the removal of these great enemies of the iron worker? I speak ignorantly.

VII. Among the range of substances I have tried, *tin* was found to yield the most conspicuous effect, after the bodies named. A fine scarlet colour is almost instantly produced when the hydrogen flame is brought into contact with tin or any alloy of tin. Tin is somewhat volatile, and its spectrum is rich in red rays. The tin must be clean; or the sulphur blue, which is much brighter, will mask the effect. A charming experiment may be made by partially scraping a soiled surface of tin; the blue and the scarlet colours mingle, and a lovely purple is the result. When a trace of phosphorus is present there may be obtained a green belt encircling a rich blue, then a purple zone, and finally a glowing scarlet at the root of the flame. These colours, it must be remembered, are not imparted to the flame, but reside on the surface of the body which the flame touches. And where the combustion of the hydrogen is complete, as in the upper part of the flame, or in the luminous stream referred to (II.), these effects are not produced, they are best developed at the root of the flame.

VIII. Passing from liquids and solids, I next tried *gases* in contact with the flame of hydrogen. Many gases imparted a colour to the flame, but here the effect was

* With all liquids, but best with mercury, a fine musical note can be obtained by causing the jet to dip just below the surface of the liquid.

different to that previously noticed. The whole flame was tinged with the colour imparted to it. A mere trace of hydrochloric acid gas imparts a reddish brown to the flame; ammonia gas gives a yellow, and burns freely. It is striking to note the combustion of ammonia gas rising from an unstopped bottle that contains the usual solution and which is placed below the flame.

But carbonic acid gas yields the most striking result in contact with the flame. A pale lilac tinge is instantly produced by a stream of this gas. This, I imagine, is due to the decomposition of the carbonic acid by the hydrogen, and the production and combustion of carbonic oxide. For it is at the lower part of the flame that the effect is most marked. One per cent. of pure carbonic acid admitted to a jar of air, can be detected on holding the jar over the flame. The breath, of course, shows the effect most strikingly.

IX. Here then is an eminently practical method of noting the presence of vitiated air in rooms or public buildings. A continuous hydrogen apparatus might be employed with a wash bulb attached. The flame might be burnt from a brass burner or lava jet, placed within a blackened tin cylinder. Opposite the flame a hole might be pierced in the cylinder, and closed by a lens for better viewing the flame within. As soon as the atmosphere in a room becomes unpleasantly vitiated the flame would indicate the fact by its changed colour. A similar apparatus might likewise be employed by miners: in metal mines as a warning against impure air, and in coal mines as a detector of fire damp. In this latter case the ends of the cylinder could be covered with wire gauze.

To this practical aspect of the question I am now giving such little leisure as I possess.

The results thus briefly described demonstrate—

1. That the combustion of hydrogen exhibits some physical peculiarities, and produces phosphorescence on many substances with which it comes in contact.

2. That the blueness so often seen in a hydrogen flame is due to the presence of sulphur, derived either from the vulcanised rubber tubing, or from atmospheric dust, or from the decomposition of the sulphuric acid spray from the generator.

3. That a flame of hydrogen forms an exceedingly delicate re-agent for the detection of sulphur or phosphorus, and possibly also of tin.

4. That many sulphates, and also carbonic acid, are apparently decomposed by a hydrogen flame.

5. That a hydrogen flame is further a test for the presence of some gases, notably carbonic acid.

6. That these results are capable of practical application.

W. F. BARRETT

International College, Spring Grove, W.

THE INHABITANTS OF THE MAMMOTH CAVE OF KENTUCKY

CRUSTACEANS AND INSECTS

(Concluded from page 448)

NEXT to the blind fish, the blind crawfish attracts the attention of visitors to the cave. This is the *Cambarus pellucidus* (Fig. 10, p. 486, from Hagen's monograph of the North American Astacidae) first described by Dr. Teikamp. He remarks that "the eyes are rudimentary in the adults, but are larger in the young." We might add that this is an evidence that the embryo develops like those of the other species; and that the inheritance of the blind condition is probably due to causes first acting on the adults and transmitted to their young, until the production of offspring that become blind becomes a habit. This is a partial proof at least that the characters separating the genera and species of animals are those inherited from adults, modified by their physical surroundings and adap-

tations to changing conditions of life, inducing certain alterations in parts which have been transmitted with more or less rapidity, and become finally fixed and habitual. Prof. Hagen has seen a female of *Cambarus Bartonii* from Mammoth Cave, "with the eyes well developed," and a specimen was also found by Mr. Cooke. Prof. Hagen remarks that "*C. pellucidus* is the most aberrant species of the genus. The eyes are atrophied, smaller at the base, conical, instead of cylindrical and elongated, as in the other species. The cornea exists, but is small, circular, and not faceted; the optic fibres and the dark-coloured pigments surrounding them in all other species are not developed." It seems difficult for one to imagine that our blind crawfish was created suddenly, without the intervention of secondary laws, for there are the eyes *more perfect in the young than the adult*, thus pointing back to ancestors unlike the species now existing. We can now understand, why embryologists are anxiously studying the embryology of animals to see what organs or characteristics are inherited, and what originate *de novo*, thus building up genealogies, and forming almost a new department of science,—comparative embryology in its truest and widest sense.

Of all the animals found in caves, either in this country or Europe, perhaps the most strange and unexpected is the little creature of which we now speak. It is an Isopod crustacean, of which the pill bug or sow bug are examples. A true species of pill bug (*Titanethes albus* Schiödte) inhabits the caves of Carniola, and it is easy to believe that one of the numerous species of this group may have become isolated in these caves and modified into its present form. So also with the blind *Niphargus stygius* of Europe, allied to the fresh water Gammarus so abundant in pools of fresh water. We can also imagine how a species of *Asellus*, a fresh water Isopod, could represent the *Idoteide* in our caves, and one may yet be found; but how the present form became a cave dweller is difficult of explanation, as its nearest allies are certain species of *Idotea* which are all marine, with the exception of two species: *I. entomon*, living in the sea and also in the depths of the Swedish lakes, as discovered by Loven, the distinguished Swedish naturalist, while a species representing this has been detected by Dr. Stimpson at the bottom of Lake Michigan. Our cave dweller is nearly allied to *Idotea*, but differs in being blind, and in other particulars, and may be called *Cacidotea stygia*.* (Fig. 11 side view, enlarged; Fig. 12 dorsal view; *b*, inner antenna; *c*, 1st leg.) It was found creeping over the fine sandy bottom, in company with the *Campodea*, in a shallow pool of water four or five miles from the mouth of the cave.

This closes our list of known articulates from this and other caves in this country, the result of slight explorations by a few individuals. The number will doubtless be increased by future research. It is to be hoped that our western naturalists will thoroughly explore all the sinks and holes in the cave country of the western and middle states. The subject is one of the highest interest in a zoological point of view, and from the light it throws on

* Generic characters. Head large, much thicker than the body, and as long as broad; subcylindrical, rounded in front. No eyes. First antennae slender, 8-jointed (2nd antennae broken off). Abdominal segments consolidated into one piece. Differs chiefly from *Idotea*, to which it is otherwise closely allied, by the 8-jointed (instead of 4-jointed 1st (inner) antennae, the very large head, and by the absence of any traces of the three basal segments of the abdomen usually present in *Idotea*. Specific characters. Body smooth, pure white; tegument thin, the viscera appearing through. Head as wide as succeeding segment, and a little more than twice as long. Inner antennae minute, slender, the four basal joints of nearly equal length, though the fourth is a little smaller than the basal three, remaining four joints much smaller than others, being one-half as thick and two-thirds as long as either of the four basal joints; ends of last four joints a little swollen, giving rise to two or three hairs; terminal joint ending in a more distinct knob, and bearing five hairs. Segment of thorax very distinct, sutures deeply incised: edges of segments pilose; abdomen flat above, rounded behind, with a very slight median projection; the entire pair of gills do not reach to the end of the abdomen, and the inner edges diverge posteriorly. Legs long and slender, 1st pair shorter, but no smaller than the second. Length .25 inch.

the doctrine of evolution. Prof. Schödte, the eminent Danish zoologist, has given us the most extended account of the cave fauna of Europe, which has been translated from the Danish into the Transactions of the Entomological Society of London (new series, vol. i., 1851).

A pertinent question arises as to the time of the formation of these caves and when they became inhabitable. As previously stated, the caves of the western and middle States are in lower Carboniferous limestone rocks, though the Port Kennedy cave explored by Wheatley and Cope* is in the Potsdam limestone. They could not have been formed under water, but when the land was drained by large rivers. This could not have occurred previous to the Triassic period. Prof. Dana in his "Manual of Geology" shows that the Triassic continent spread westward from the Atlantic coast "to Kansas, and southward to Alabama; for through this great area there are no rocks more recent than the Paleozoic." "Through the Mesozoic period (comprising the Triassic, Jurassic, and Cretaceous periods) North America was in general dry land, and on the east it stood a large part of the time above its present level." Though at the close of these periods there was a general extinction of life, yet this was not probably a sudden (one of months and even years), but rather a secular extinction, and there may be plants and animals now living on dry land, which are the lineal descendants of Mesozoic and more remotely of Carboniferous forms of life. So our cave animals may possibly be the survivors of Mesozoic forms of life, just as we find now living at great depths in the sea remnants of Cretaceous life. But from the recent explorations in the caves of Europe and this country, especially the Port Kennedy cave, with its remarkable assemblage of vertebrates and insects, we are led to believe from the array of facts presented by Prof. Cope that our true subterranean fauna probably does not date farther back than the beginning of the Quaternary, or post-Pliocene, period. We quote his "general observations" in his article on the Port Kennedy fauna:—

"The origin of the caves which so abound in the limestones of the Alleghany and Mississippi valley regions, is a subject of much interest. Their galleries measure many thousands of miles, and their number is legion. The writer has examined twenty-five, in more or less detail, in Virginia and Tennessee, and can add his testimony to the belief that they have been formed by currents of running water. They generally extend in a direction parallel to the strike of the strata, and have their greatest diameter in the direction of the dip. Their depth is determined in some measure by the softness of the stratum whose removal has given them existence, but in thinly stratified or soft material, the roofs or large masses of rocks fall in, which interrupt the passage below. Caves, however, exist when the strata are horizontal. Their course is changed by joints or faults, into which the excavating waters have found their way.

"That these caves were formed prior to the post-Pliocene fauna is evident from the fact that they contain its remains. That they were not in existence prior to the drift is probable, from the fact that they contain no remains of life of any earlier period so far as known, though in only two cases, in Virginia and Pennsylvania, have they been examined to the bottom. No agency is at hand to account for their excavation, comparable in potency and efficiency to the floods supposed to have marked the close of the glacial epoch, and which Prof. Dana ascribes to the Champlain epoch. An extraordinary number of rapidly flowing waters must have operated over a great part of the Southern States, some of them at an elevation of fifteen hundred feet and over (perhaps two thousand) above the present level of the sea. A cave

in the Gap Mountain, on the Kanawha river, which I explored for three miles, has at least that elevation.

"That a territory experiencing such conditions was suitable for the occupation of such a fauna as the deposits contained in these caves reveal, is not probable. The material in which the bones occur in the south is an impure limestone, being mixed with and coloured by the red soil which covers the surface of the ground. It is rather soft but hardens on exposure to the air.

"The question then remains so far unanswered as to whether a submergence occurred subsequent to the development of the post-pliocene mammalian fauna. That some important change took place is rendered probable by the fact that nearly all the neotropical types of the animals have been banished from our territory, and the greater part of the species of all types have become extinct. Two facts have come under my observation which indicate a subsequent submergence. A series of caves or portions of a single cave once existing on the south-east side of a range of low hills among the Alleghany mountains in Wythe Co., Virginia, was found to have been removed by denudation, fragments of the bottom deposit only remaining in fissures and concavities, separated by various intervals from each other. These fragments yielded the remains of twenty species of post-Pliocene mammalia.* This denudation can be ascribed to local causes, following a subsidence of uncertain extent. In a cave examined in Tennessee the ossiferous deposit was in part attached to the roof of the chamber. Identical fossils were taken from the floor. This might, however, be accounted for on local grounds. The islands of the eastern part of the West Indies appear to have been separated by submergence of larger areas, at the close of the period during which they were inhabited by post-Pliocene mammalia and shells. The caves of Anguilla include remains of twelve vertebrates;† of which seven are mammalia of extinct species, and several of them are of large size. These are associated with two recent species of molluscs, *Turbo pica* and a *Tudora* near *pupaeformis*.‡ As these large animals no doubt required a more extended territory for their support than that represented by the small island Anguilla, there is every probability that the separation of these islands took place at a late period of time and probably subsequent to the spread of the post-Pliocene fauna over North America."

I think the reader will conclude from the facts Prof. Cope so clearly presents, that the subterranean fauna of this country does not date back beyond the Quaternary period. These species must have been created and taken up their abode in these caves (Mammoth Cave and those of Montgomery County, Virginia) after the breccia flooring their bottoms and containing the bones of Quaternary animals had been deposited; or else migrated from Tertiary caves farther south, which is not probable, as it has been previously shown that those blind animals inhabiting wells immediately die on being exposed to the light. (British Sessile-eyed Crustacea, i. p. 313. Though this is true of the Gammaridae, Mr. Putnam tells me that a blind crawfish lived several days in a bottle of water exposed to the light, and is thus as hardy as any crustacean.)

* See Proceed. Amer. Phil. Soc., 1869, 171.

† Loc. cit. 1869, 183; 1870, 608. A fourth species of gigantic Chinchillid has been found by Dr. Rijgersma, which may be called *Loxonychia pygmaea* Cope. It is represented by portions of jaws and teeth of three individuals. It is one of the largest species, equalling the *L. latidens*, and has several marked characters. Thus the roots of the molars are very short, and the triturating surface oblique to the shaft. The roots of the second and fourth are longer than those of the first and third. The last molar has four dental columns instead of three as in the other *Loxonychia*, and is triangular or quadrant-shaped in section; the third is quadrangular in section, and has three columns. The second is the smallest, being only $\frac{1}{6}$ the length of the subtriangular first. Length of dental series m. .63 or .25 inches. Palate narrow and deeply concave. There is but little or no lateral contraction in the outlines of the teeth; the shanks are entirely straight. In its additional dental column, this species approaches the genus *Amblyrhiza*. The large Chinchillas of Anguilla are as follows, *Loxonychia longidens*, *L. latidens*, *L. quadens*, and *Amblyrhiza insularis*.

‡ See Bland, Proceed. Amer. Phil. Soc., 1871, 58.

* * A notice of the animals found in this cave will be found in the Proc. Amer. Phil. Soc., April 1871. The insects there enumerated would probably not come under the head of cave insects.

Assuming, on the principles of evolution, that the cave animals were derived from other species changed by migration from the outer world to the new and strange regions of total darkness, it seems evident that geologically speaking, the species were suddenly formed, though the changes may not have been wrought until after several thousand generations. According to the doctrine of natural selection, by which animal species pass from one into another by a great number of minute variations, this time was not sufficient for the production of even a species, to say nothing of a genus. But the comparatively sudden creation of these cave animals affords, it seems to us, a very strong argument for the theory of Cope and Hyatt, of

Hadenacrus subterraneus and *stygius*. The Carabid beetle, *Anophthalmus*, extending farther into the cave, would lose its wings (all cave insects except the Diptera have no wings, clytra excepted) and eyes, but as nearly all the family are retiring in their habits, the species hiding under stones, its form would not undergo further striking modification. So with the blind *Campodea*, which does not differ from its blind congeners which live more or less in the twilight, except in its antennæ becoming longer. The blind *Adelops*, but with rudiments of eyes, does not greatly depart in habits from *Catops*, while on the other hand the remarkable *Stagobius* of the Illyrian caves, which according to Schiödte spends its life in crawling ten to twenty feet above the floors over the columns formed by the stalactites

FIG. 10.—*Cambarus pellucidus*.

creation by acceleration and retardation. The strongly marked characters which separate these animals from their allies in the sunlight, are just those fitting them for their cave life, and those which we would imagine would be the first to be acquired by them on being removed from their normal habitat.

On introducing the wingless locust, *Certhophilus maculatus* into a cave, where it must live, not under stones, but by clinging to the walls, its legs would tend to grow longer, its antennæ and palpi would elongate and become more delicate organs of hearing as well as touch,* and the body would bleach partially out, as we find to be the case in

* After writing this article, and without the knowledge of his views, we turned to Darwin's "Origin of Species" to learn what he had to say on the origin of cave animals. He attributes their loss of sight to disuse, and remarks:—"By the time an animal has reached, after numberless generations, the deepest recesses, disuse will on this view have more or less perfectly ob-

FIG. 11.—*Cecidotea stygia* (side view).

to which unique mode of life it is throughout perfectly adapted, is remarkably different from other Silphids. Its legs are very long and inserted far apart (the prothorax being remarkably long), with surprisingly long claws, while the antennæ, again, are of great length and densely clothed with hairs, making them most delicate sense organs.* So also are the limbs of the false scorpion, and the spider and pill bug (*Titanethes*) of remarkable length.

FIG. 12.—*Cecidotea stygia* (dorsal view).

But the modifications in the body of the *Spirostrephon* are such that many might deem its aberrant characters as of generic importance. It loses its eyes, which its nearest allies in other, but smaller, caves possess, and instead gains in the delicate hairs on its back, which evidently form tactile organs of great delicacy; the feet are remark-

literated its eyes, and natural selection will often have effected other changes, such as an increase in the length of the antennæ or palpi, as a compensation for blindness." (5th Amer. Edit., p. 143.) We are glad to find our views as to the increase in the length of the antennæ and palpi compensating for the loss of eyesight, confirmed by Mr. Darwin.

* Schiödte remarks that "it is difficult to understand the mode of life of *Stagobius troglodytes*, or how this slow and defenceless animal can escape being devoured by the rapid, piratical Arachnids, or find adequate support on columns, for inhabiting which it is so manifestly constructed. We are led in this respect to consider the antennæ. Whatever significance we attach to those enigmatical organs, we must admit that they are organs of sense, in which view an animal having them so much developed as *Stagobius*, must possess a great advantage over its enemies, if these be only Arachnids. Its cautious and slow progress, and its timid reconnoitring demeanour, fully indicate that it is conscious of life being in perpetual danger, and that it endeavours to the utmost to avoid that danger. Darkness, which always favours the pursued more than the pursuer, comes to its aid, especially on the uneven excavated surface of the columns."

ably long, as also the antennæ. These are not new formations, but simply modifications apparently, by use or disuse of organs present in the other species. The aberrant myriopod and Stagobius are paralleled by the blind fish, an animal so difficult to classify, and so evidently adapted for its abode in endless darkness. And as an additional proof of the view here taken that these cave animals are modified from more or less allied species existing outside of the caves, we have the case of the crawfish, whose eyes (like those of the mole), are larger in the young than in the adult, indicating its descent from a species endowed with the faculty of sight, while in the adult the appendages are modified as tactile organs so as to make up for its loss of eyesight, in order that it may still take its prey.

We thus see that these cave animals are modified in various ways, some being blind, others very hairy, others with long appendages. All are not modified in the same way in homologous organs; another argument in proof of their descent from ancestors whose habits varied as those of their out-of-door allies do at present. Had they been specially created for subterranean life, we should have expected a much greater uniformity in the organs adapting them to a cave life than we actually find to be the case.

Another fact of interest in this connection is the circumstance that these cave species breed slowly, being remarkably poor in individuals; they are nearly all, except the wingless grasshoppers, extremely rare. Did they breed as numerous as their allies in the outer world, the whole race would probably starve, as the supply of food even for those which do live is wonderfully limited.

It is now known that animals inhabiting the abysses of the sea are often highly coloured: light must penetrate there, for we know that were the darkness total they would be colourless like the cave insects.

In view of the many important questions which arise in relation to cave animals, and which have been too imperfectly discussed here, we trust naturalists the world over will be led to explore caves with new zeal, and record their discoveries with minuteness, and the greatest possible regard to exactness. The caves of the West Indian Islands should first of all be carefully explored. Also those of Brazil, those of the East Indies, and of Africa, while fresh and more extended explorations of our own Mammoth Cave should be made, perhaps by a commission acting under Government or State authority, in order that the most ample facilities may be afforded by the parties owning the cave.

A. S. PACKARD

PROPOSED GRAND AQUARIUM FOR MANCHESTER

THE *Manchester Examiner* and *Times* of April 2 gives a long account of a Grand Marine Aquarium which it is proposed to build at Manchester, and which shows the interest which is felt in scientific studies in the northern capital. From this article we have made the following extracts, as showing the complete scale upon which everything is proposed to be carried out.

The funds are to be raised by a company started under the superintendence of a number of gentlemen resident in the city who are interested in marine zoology, and desire to promote scientific education in all its branches. The building will contain all the recent improvements shown to be necessary at the Crystal Palace and Brighton Aquaria, and will be rectangular in shape, 120 ft. long and 70 ft. wide. This space will be divided into two side galleries, each 120 ft. long and 15 ft. wide, separated from the central saloon by a light screen. Running along one side of each of these galleries will be a series of tanks, about eighty in number, forty in each gallery, varying in capacity from 300 to 3,000 gallons, and the roofs will be so arranged that the light will pass through the water at an angle of about forty-five degrees

to the spectators, thus rendering distinctly visible the living inhabitants and plants contained in the grotto-like tanks. The grand saloon will be also 120 ft. long by 40 ft. wide, supporting on light iron columns an open panelled roof. All the windows will be so arranged as to admit only the exact quantity of light required, as it is found that an excess of light acts upon the higher marine plants and animals in a manner directly contrary to its action upon terrestrial life. It blanches them in a similar manner as ordinary plants are blanched by being earthed up. The most brilliant coloured marine plants are those which live in comparative darkness. The grand saloon will contain two tanks—the largest that have yet been constructed—one at each end of the room, 30 ft. long, 10 ft. wide, and 8 ft. deep, capable of containing each 15,000 gallons of water, and in which the largest specimens of fish found in the British seas will find ample room to display themselves. These tanks will have also a polished plate-glass frontage of great strength, through which the animals can be well seen.

In order to accommodate the inhabitants of what is called the littoral zone round our coasts, a series of shallow tanks, varying in capacity from 20 to 200 gallons, will be erected, in which the animals can be seen either from the surface of the water or through the transparent fronts, and by an ingenious contrivance the supply of water will be so regulated as to afford in every respect tidal currents. Besides these there will be other tanks at the back of the exhibition tanks for reserve stocks, and in the basement cisterns to hold a reserve supply of 60,000 gallons of sea water.

Such are the contemplated arrangements for marine, animal, and vegetable life; but in addition to these the inhabitants of our brooks, ponds, &c., will not be forgotten, and a series of table aquaria will be provided: while the larger inhabitants of our rivers and lakes will swim in an ever-flowing river and pond supplied by fountains, and placed in the centre of the grand saloon. Such is a brief description of the proposed Manchester Grand Aquarium, which, it is hoped, will both be a success in a scientific, as well as a pecuniary point of view. Mr. B. Hooper, a well-known naturalist, has been engaged as curator of the Aquarium. A site for the Aquarium has been obtained in the vicinity of the Alexandra Park, and it is proposed to open it on Saturdays and Mondays at an admission fee of 1d.; on Tuesdays, Wednesdays, and Thursdays, at 6d.; and on Friday, which will be a students' day, at 1s.

NOTES

THE following lectures in Natural Sciences will be delivered in Trinity, St. John's, and Sidney Sussex Colleges, Cambridge, during Easter Term, 1872:—"On Light and Heat" (for the natural sciences tripos), by Mr. Trotter, Trinity College; Mondays, Wednesdays, and Fridays, at 10, commencing Wednesday, April 17. "On Heat" (for the special examination for the ordinary degree), by Mr. Trotter, Trinity College; Tuesdays, Thursdays, Saturdays, at 11, commencing Tuesday, April 16. "On Chemistry," by Mr. Main, St. John's College; Mondays, Wednesdays, Fridays, at 12, in St. John's College Laboratory, commencing Friday, April 19. Instruction in Practical Chemistry will also be given. Attendance on these lectures is recognised by the University for the certificate required by medical students previous to admission for the examination for the degree of M.B. "On Palæontology" (the Mollusca), by Mr. Bonney, St. John's College; Wednesdays and Fridays, at 9, commencing Friday, April 19. "On Geology" (for the natural sciences tripos. Stratigraphical Geology), by Mr. Bonney, St. John's College; Tuesdays, Thursdays, and Saturdays, at 10, commencing Thursday, April 18. There will be excursions every Saturday. "Elementary Geology" (for the special examination); Wednesdays

and Fridays, at 11, commencing Friday, April 19. "On Botany," by Mr. Hicks, Sidney College; Mondays, Wednesdays at 1 P.M., and Fridays, at 12, beginning Monday, April 15. The lectures this term will be chiefly on Cryptogamic Botany, the movements of plants, and the principles of classification. "On Embryology," the Trinity Praeceptor in Physiology (Dr. M. Fostey) will deliver a short course at the new museums, beginning Monday, April 22, at 11 o'clock. The Physiological Laboratory is open for practical instruction in Physiology to all those who have gone through the elementary course.

WE have to record this week the death of *facile princeps* the most eminent of vegetable physiologists, Prof. Hugo von Mohl, which took place on April 1 at Tübingen. Von Mohl was born at Stuttgart in 1805, and in 1835 was appointed Professor of Botany and director of the Botanic Garden at Tübingen, a position he has held ever since. Conjointly with Schlechtendal, and since his death with Prof. de Bary, formerly one of his pupils, he has been editor of the weekly "Botanische Zeitung" since its commencement in 1843. He was one of the foreign members of the Linnean Society, having been elected as long ago as 1837. Von Mohl has been a copious and most accurate writer on subjects connected with vegetable anatomy and physiology, of which he may be said to have laid the secure foundation in his early investigations of the true relations of cell-membrane and contents. Among his original observations we may especially mention his essay on the Structure of Endogens, published by von Martius in his "Historia Palmarum," and on the Stem-structure of Cycads in the "Vegetable Cell," which appeared in Rudolph Wagner's "Handwörterbuch;" on the Origin and Structure of Stomates; on Cuticle; on the Structure of Cell-membrane; on the Structure and Anatomical relations of Chlorophyll; on the Multiplication of Plant-cells by division, and numerous other essays collected in his "Vermischte Schriften."

ASTRONOMY has sustained a heavy loss in the death of M. P. A. E. Laugier, which took place at Paris on the 5th inst., in the 50th year of his age. M. Laugier was a member of the French Academy and of the "Bureau des Longitudes," and examiner to the naval school at Brest. He was a pupil of Arago, and the following account of his various researches is furnished to the *Revue Scientifique* by M. G. Rayet:—"In 1841 he presented a memoir to the Academy on Solar Spots, and was the first to determine their proper motion. The discovery and calculation of a telescopic comet in 1842 won for the young astronomer the Lalande gold medal. At the request of Humboldt he was engaged for some years in the improvement of the construction of astronomical clocks. In 1853 he made an exact determination of the latitude of the Paris Observatory, estimating it at $48^{\circ} 50' 11''$, differing considerably from the earlier determination of Arago and Mathieu. In 1857 he published a catalogue of the declination of 140 stars, having previously issued one of 53 nebulae. M. Laugier was associated with Arago in a number of his researches on the physics of the globe, and in his magnetic and photometric labours; and has for long made the observations on the declination and inclination of the magnet for the "Bureau des Longitudes." M. Rayet speaks of his death as a source of great grief to the Academy, which had formerly elected him president, and to his colleagues, by whom he was beloved for the moderation of his character, and his affable manners.

At the meeting of the French Academy of Sciences on the 1st inst. the Abbé David and M. Ledieu were elected correspondents of the Section of Geography and Navigation, in the room of M. d'Abbadie, who has been elected a member of the Academy, and of the late Prince Demidoff.

THE Museums and Lecture Room Syndicate have presented

their sixth Annual Report to the Senate of the University of Cambridge. It includes separate reports from Mr. J. W. Clark, superintendent of the Museum of Zoology and Comparative Anatomy, and from Profs. Humphry, Newton, Babington, Miller, Challis, Living, and Sedgwick. In response to an appeal from the venerable Prof. Sedgwick, the Woodwardian Museum has acquired during the past year (the purchase money having been raised by subscription) the very valuable collection of fossils made by Mr. Leckenby of Scarborough. Prof. Sedgwick considers the present geological collection of the University to be one of the noblest collections, as far as regards British geology, that exists in England, and for study and practical use, to be inferior to none existing in the island. In order to supply facilities for the practical study of Comparative Anatomy, and to supplement the lectures of Prof. Newton, Mr. J. W. Clark has commenced a class for practical work, for which, however, no sufficient accommodation is at present provided by the University. Mr. G. R. Crotch has been engaged for nearly the last twelvemonth in determining and arranging the extensive collections of insects, both British and exotic, contained in the Museum. The collection includes long series of those insects which were peculiar to certain localities in Cambridgeshire and the adjoining counties, and which, from increase of drainage in the fens and other causes, are either extinct or likely to become so in a few years.

THE discovery of two new planets is recorded. The elements of the first, No. 119, discovered by M. Paul Henry at Paris, are:—

April 9, 11^h, Paris M.T. R.A. = $13^{\text{h}} 18^{\text{m}} 59^{\text{s}}$. $D. \pm -8^{\circ} 40' 23''$.
The first position is approximate only. The horary movement is $-1^{\text{s}} 75$ R.A., + $25''$ declination. It is of the 11th magnitude. The second was discovered by M. Borely, and has the following elements:—

April 10, 12^h 16^m 32^s, Marseilles M.T. R.A. 12^h 0^m 55^s. 38.
Polar distance, $95^{\circ} 2' 44''$.
April 10, 13^h 14^m 36^s, Marseilles M.T. R.A. 12^h 0^m 53^s. 63.
Polar distance, $95^{\circ} 2' 41''$.
It is between the 11th and 12th magnitude.

THE next lecture to the Crystal Palace School of Science will be delivered this evening by Dr. W. B. Carpenter on "Researches in the Deep Sea."

DR. LIEBREICH will deliver his lecture on "Turner and Mulready" at the London Institution, Finsbury Circus, on Thursday evening next, the 25th inst., at 7.30 P.M.

THE following paragraph, copied *verbatim et literatim* from an evening contemporary, is a striking comment on our remarks last week on "Newspaper Science:—" "M. Agassiz has been finding out some more curious creatures in the deep-sea dredgings near Rio. It would really seem that if we only go deep enough we shall eventually reach the beginning of all things. Dr. Carpenter found living at the bottom of the Atlantic crustaceans of the same kind as those whose bodies now lie in our chalk hills, only seeming slightly degenerated, as if the family had once 'seen better days.' And now Prof. Agassiz tells his friend Prof. Peirce, of Harvard, in a long letter published in the American papers, how at 500 fathoms down he has fished pectens, and also other creatures, who are henceforth to bear the fearful but doubtless honourable appellation of Tomocarids Peircei, which resemble nothing living, only fossils of some of the earliest formations. The Tomocarids, in particular, is strongly suspected of being—we blush to name it—no better than a Trilobite! We shall not disturb our readers by quoting all the array of terrible words—maxillipeds, pygidiums, phyllopods, and the like—with which Prof. Agassiz's letter bristles; nor his interesting controversy with Prof. Milne Edwards concerning the Simulus, which

animal's 'cephalo thorax' is so remarkable that 'the function of chewing is devolved upon the legs.' We only advise our friends who may be intensely anxious about these points to consult his letter *in extenso*. Is the author of "What is a Joule?" the special scientific correspondent of all the daily papers?

We learn from the *Journal of the Society of Arts* that King Victor Emmanuel has presented to the Geological Museum of the University of Rome a collection of Peruvian antiquities—silver vases, curious musical instruments, a coloured garment made from the bark of trees, and arrows and lances. The articles were discovered in a guano bed, and are antiques. The lances are notched, ornamented with feathers, and have wooden heads, showing that they were made before iron was used.

A REPORT of the meeting of delegates of the French departement learned societies, held on the 4th inst., under the presidency of M. Jules Simon, is given in *Les Mondes*. The following medals were awarded:—Gold: to Grenier, of Besançon, botanical researches; Grandidier, scientific travels in Madagascar; Houzeau, of Rouen, researches in ozone. Silver: to Boussinesq, of Gap, mathematical mechanics; Tourdes, of Strasboarg, legal medicine; Faivre, of Lyons, vegetable physiology; Fromontel, of Gray, palæontology; Reboul, of Besançon, chemistry; Cailletet, of Châtillon-sur-Seine, agricultural and industrial chemistry; Mazare, of Bar-le-Duc, agriculture; Chautard, of Nancy, meteorology; Coquelin, of Beauficel, meteorology; Crova, of Montpélier, physics; Raoult, of Grenoble, physics; Mussy, of Montluçon, a geological map of Ariège.

PROF. HAYDEN has applied to the Congress of the United States for a grant of 75,000 dols. for the purpose of continuing for another year his most important geological survey of the territories of the United States. He proposes making a thorough series of astronomical, topographical, meteorological, geological, and chemical observations, which cannot but be of the utmost value in developing the material resources of the country. The application has the cordial support of the Secretary of the Interior.

SCIENTIFIC INTELLIGENCE FROM AMERICA*

MAJOR POWELL has returned from the cañons of the Colorado, having left his party in the field in charge of Prof. Thompson. Since the party started in April last, it has passed through the cañons of Green River and the cañons of the Colorado to the mouth of the Paria, at the head of Marble Cañon. Here the Major left his boats for the winter, and he expects to return as soon as there is a favourable stage of water, and embark for the second trip through the Grand Cañon. On the way down the party explored the region to the west of the Green and Colorado, tracing the courses of the larger streams emptying into the two great rivers to their sources in the Wasatch Mountains and Sevier Plateau, and examined the geology of the great mesas and cliffs. Early in the winter a base line 47,000 feet in length was measured on a meridian running south from Kanab, and the party is now engaged in extending a system of triangles along the cliffs and peaks among lateral cañons of the Colorado. During the past season the party has discovered many more ruins of the communal houses once occupied by the prehistoric people of that land. Many of these houses stood upon the cliffs overhanging the cañons, and many more are found in the valleys among the mountains to the west. Stone implements, pottery, basket-ware, and other articles were found buried in some of the ruins. The Major found a tribe of Utes on the Kaibab Plateau who still make stone arrow-heads and other stone implements, and he had an opportunity to observe the process of manufacturing such tools.—Mr. Joseph Sullivan, of Columbus, Ohio, a well-known naturalist, publishes an account in the *Ohio State Journal* of the capture of the *Bassarotis astuta*, or ring-tailed cat of the Rio Grande region. It was

taken in Fairfield County, Ohio, and was said to be accompanied by a second specimen. The occurrence of this animal so far north is very remarkable, and it may be a question whether it had not been brought from Mexico or California, and escaped from confinement. It is an animal very much sought after as a pet, being clean in its habits, and readily becoming very tame and affectionate; indeed, it would seem to be quite a desirable animal to domesticate and keep about the house as a protection against rats and mice. Some years ago a specimen of this same animal was brought into the Smithsonian Institution, having been captured in a hen-coop near the city. It was in capital condition and in full fur; but it had evidently escaped from captivity, as shown by the marks of the rubbing of a collar round the neck.—The greatest depth between the west end of Cuba and the coast of Yucatan found by the Coast Survey steamer *Bibb* is 1,164 fathoms, as reported to Prof. Peirce by Captain Robert Platt, commanding the surveying vessel. The lowest temperature observed is 39.5° F. at the bottom; surface, 81°; strongest current, two knots; direction, north. Dr. Stimpson reports the bottom from Cape San Antonio to Yucatan very barren of animal life. A few rare shells were found.—In a paper by Prof. Cope upon the *Pythonomorpha*, or Python-like fossil saurians of the cretaceous formation of Kansas, presented to the Academy of the American Philosophical Society of Philadelphia, he shows that America is the home of this group, four species only having been described from Europe. Forty-two North American species are already known, of which fifteen belong to the Greensand formation of New Jersey, seven to the Limestone region of Alabama, seventeen to the Chalk of Kansas, and three to other localities. Of the Kansas species six are described as new by Prof. Cope in the paper referred to.—A new fossil reptile, from the cretaceous strata of Kansas, has just been described by Prof. Cope under the name of *Cynocercus incisus*. The peculiarity of this reptile consists in having the articular faces of the vertebrae deeply excavated above and below, so as to give them a transverse character. A new crocodilian from the same region was also described, under the name of *Hyposaurus webbi*.—Prof. Cope has shown, in a paper read to the American Philosophical Society, that the greater number of the fossil fishes of the cretaceous strata of Kansas belong to three families, namely, the *Saurodontidae*, the *Pachyrhizodontidae*, and the *Stratodontidae*. Of the first family four genera and ten species are described in his paper, some of them (as those of the genus *Porteus*) being among the most formidable of marine fishes. Of the second family one genus and four species are introduced, and three genera and seven species of the third. The *Stratodus*, a genus of the *Stratodontidae*, is provided with multitudes of minute shovel-headed teeth. He finds a great resemblance between this Kansas fauna and that of the English Chalk, no less than six of the eight Kansas genera having been found in the latter.—Some of our readers may remember the letter written by Prof. Agassiz to Prof. Peirce in December 1871, just before starting upon the Hassler expedition, in which he announced beforehand the general nature of the discoveries that he expected to make. His ability to make these predictions with any degree of certainty was much questioned by those who were not familiar with the method of research in natural history, and of the almost mathematical nature of the inferences to be derived from certain given premises. We now have a second letter addressed to Prof. Peirce, written at Pernambuco on Jan. 16, giving an account of experiences up to that date, which go far toward showing that the Professor really knew of what he was speaking in the first instance. Owing to various adverse influences, among them the necessity of hastening with all possible despatch to reach the Straits of Magellan at the earliest possible date, only four hauls of the dredge were made in water of any great depth, those being at depths of from 75 to 120 fathoms off Barbadoes. The results of these were in the highest degree satisfactory, however, "the extent and variety of material obtained being enough to occupy," in the Professor's words, "half a dozen competent zoologists for a whole year, if the specimens could be kept fresh for that length of time." As anticipated by the Professor in the letter referred to, the most interesting discoveries were certain forms of animals, the allies of which had previously been known in greater part or entirely as fossils of older formations. Among these may be mentioned a remarkable sponge, a crinoid very much like *Rhizocrinus*, a living *Pleuronomaria*, only three having been previously known, although a great many are described as fossil, &c. The crinoid, especially, is one of the very few living representatives of what was originally the prevailing character of

* Communicated by the Scientific Editor of *Harper's Weekly*.

the marine fauna of the silurian and other epochs; and while now they occur only in the very deepest water, they were formerly found crowded in the shallower seas. The inquiry, therefore, suggested itself to the Professor as to the reason of this difference, and he makes the suggestion that in the progress of the earth's growth we may look to such displacement of conditions favourable to maintaining certain low types as may recall most fully the adaptation to former ages, and that the deeper waters of the present constitution of our globe possibly approximate the conditions of animal life in the shallow seas of former ages as nearly as anything can in the present order of things on the earth. The depth of the ocean alone, he thinks, can place animals under the high pressure which the heavier atmosphere of the earlier period afforded. But as such pressure cannot be a favourable condition for the development of life, it is to be expected that the lower forms only will occur in the deep seas. Other causes acting in the same direction are the decrease of light in the greater depths, the smaller amount of free oxygen, the reduced amount and smaller variety of nutritive substances, &c. He does not think, however, that facts warrant the conclusion that any of the animals now living are lineal descendants of those of the earlier ages, nor that we may justly assume that the cretaceous formation is still extant, notwithstanding the similarity of forms. It would be just as true to nature to say that the tertiary period is exhibited in the tropics, on account of the similarity of the Miocene mammalia and those of the torrid zone.—The ninth number of the illustrated work on the butterflies of North America, in course of publication by Mr. William H. Edwards, has just made its appearance, and we are informed that the tenth number, to appear very shortly, will conclude the first volume. This number, like its predecessors, is accompanied by a great many quarto plates in the highest style of pictorial excellence, depicting some extremely beautiful species and varieties of butterflies. Among these are three varieties of *Papilio Ajax*, namely, *Walshii*, *telamonides*, and *Marcellus*. Mr. Edwards, in his paper, makes some judicious remarks upon the uncertainty that exists in regard to the true character of many butterflies which some naturalists consider as perfectly distinct species, and others as mere varieties. He takes the ground that the only way of coming to a satisfactory conclusion is to breed them, and ascertain whether the eggs from the same female develop similar larvæ or not, and whether these, even if different, produce the same perfect insects or different ones. The attempt at discriminating from the perfect insect alone he considers extremely unsatisfactory.

ANNUAL ADDRESS TO THE GEOLOGICAL SOCIETY OF LONDON, FEB. 16, 1872

By J. PRESTWICH, F.R.S., PRESIDENT

(Concluded from p. 472.)

IT has been urged as a fatal objection to the discovery of coal in the south-east of England, that the Coal Measures become unproductive and thin out under the Chalk, as they range from Valenciennes towards Calais, and, therefore, that the coal-trough or basins end there. It is perfectly true that the Coal Measures do thin out between Bethune and Calais, but not in the sense of their dying out owing to their deposition near the edge of a basin. In that case, each seam, each stratum, would gradually become thinner and disappear; but such is not the fact. None of the beds of the Belgian coal-field are thick. The average does not exceed 2½ feet. At Valenciennes it is the same; whereas M. Burat states the mean thickness of the beds actually increases westward of Bethune to more than 2½ feet. With respect also to the extreme end of this basin, the lower beds there brought up correspond with the bottom beds of the Hainault basin, where the lower 650 feet consist of unproductive measures. The thinning-out is, in fact, due to denudation, just as the Bristol coal-field thins out at Cromhall to resume in the Forest of Dean, or the coal-field of Liège thins out at Nameche to resume at Namur in the great field of Charleroi and Mons.

The deterioration of the coal in the small coal-field of Hardingham, near Boulogne, has also been adduced against the occurrence of workable coal in South-Eastern England, but Mr. Godwin-Austen has shown that this Hardingham coal-field is one of those small local developments of coal-bearing strata intercalated in the Mountain Limestone, and is of older date than the great

Belgian coal-field. It has, therefore, no bearing on this part of the question.

Another objection to which much weight has been attached is that the coal-field of Bath and Bristol forms an independent basin, cut off both on the east and on the west by ridges of Millstone Grit and Mountain Limestone, so that there is an end of the eastern extension of the Coal Measures. This is quite correct as far as regards the western edge, and is probably the case on the eastern, although as the edge of the basin is there covered by Secondary rocks, some uncertainty still exists about the disposition of the Palæozoic rocks under them. Admitting, however, the basin to be complete and isolated, that is no proof that the older Palæozoic rocks prevail exclusively to the east; for the Coal Measures of the Somerset basin maintain their full development to the edge of the basin, and are there cut off by denudation, and are not brought to an end by thinning out. They form really part of a more extended mass, of which we have there one fragment; while on the west another portion exists in the Welsh basin, and another in the newly discovered small basin of the Severn valley.

This last basin is entirely covered by the New Red Sandstone; and as the Welsh basin is bounded on the east and the Bristol basin on the west by Mountain Limestone, the same argument as the one above might have been used to show the impossibility of coal occurring in this intermediate area.

But the fact is, it is the very nature of this great line of disturbance to have minor rolls and flexures of the strata at, or nearly at, right angles to it, and so causing breaks in the coal-trough, which would otherwise flank it without interruption; thus the Aix-la-Chapelle coal-field is separated by older rocks from that of Liège, which is again separated by a ridge of Mountain Limestone from that of Hainaut. So in the case of south-western England, we have the several basins of South Wales, Severn Valley, and Bristol, separated by tracts of Mountain Limestone and Old Red Sandstone, the extremes of the intervening belts of older rocks being two miles at Nameche and eighteen miles in Wales. These barriers are clearly only local, and the division of the Coal Measures into separate basins appears to be their ordinary condition along this great line of disturbance. The length of the two known portions of the axis included between Pembroke and Frome, and between Calais and Westphalia, is 472 miles, and in this distance we find eight separate and distinct coal-fields. The combined length of these eight coal-fields is about 350 miles, leaving about 122 miles occupied by intervening tracts of older rocks; so that nearly three-quarters of the whole length is occupied by coal-strata. I consider that a structure which is constant (so far as the axis of disturbance can be traced above ground) is, in all probability, continued under ground in connection with the range of the same line of disturbance; and I see no reason why the coal-strata should not occupy as great a proportionate length and breadth in the under-ground and unknown, as in the above-ground and explored area.

With respect to the possibility of denudation having removed the intervening Coal Measures, enormous as the extent of denudation must have been previous to the deposition of the Permian strata, we cannot admit its exceptional action in this case. Denudation has removed from the crest of the Mendips a mass of strata possibly equal to two miles or more in height, and from that of the Ardennes as much as three or four miles, and it has also worn extensive channels between many of our coal-fields, so that the power of such an agent cannot be denied. But it is a power of planing down exposed surfaces rather than of excavating very deep troughs. Notwithstanding its immense planing-down action on the Mendips and Ardennes, deep troughs of Coal Measures are left flanking their northern slopes. These troughs descend to more than a mile beneath the level of the sea; and I do not think it probable that those underground intermediate portions of the trough where the axis is lower, would have suffered more than those on the higher levels, unless it were to the extent caused by the later denudation which preceded the Cretaceous period. But this would not affect the main bulk of the Coal Measures. The Belgian coal-field, which was exposed to the action of both these denudations, still retains vast proportions.

I may remark that the pre-Cretaceous denudation was very irregular in its action. At one place near Mons the Chalk and Tertiary strata are above 900 feet thick; whilst at another, on about the same level, and at but a short distance, they are not 100 feet thick—an old under-ground hill of highly inclined

Coal Measures causing this difference, and rising in the midst of the unconformable newer strata. This shows that in the English Chalk area we may possibly find irregular old surfaces of this kind, so that the Coal Measures may exist at places nearer the surface than we have estimated.

We have alluded before to the great length and narrow width of the Belgian coal-fields. That of Liège is forty-five miles long, with a mean width of less than four miles, whilst that of Hainaut and Valenciennes is 119 miles long, with a width scarcely greater. The presence of lower Carboniferous rocks under Harwich, and the wider range north and south of the Bristol coal-field, renders it possible that the trough in the intermediate area may have a greater expansion than in Belgium; but we have nothing else to guide us, unless it be that the lateral pressure in the intermediate ground was probably less than in the Ardennes and the Mendips, where it has exercised its maximum elevatory force. In that case the coal-trough in this intermediate area would be less compressed and more expanded; so we might consequently here look to find larger coal-basins than either those of Somerset or Liège. The position of these basins I am disposed, for reasons given in my Report, to place farther north than Mr. Godwin-Austen, and should therefore look for them not in the valley of the Thames, or on the line of the North Downs, but under South Essex, Middlesex or Hertfordshire, Oxfordshire, and North Wiltshire.

The strata on the south side of the Liège coal-field rise abruptly against highly inclined and faulted Devonian rocks, and the north side they rise at a less angle beneath Cretaceous or Tertiary strata. In the Hainaut coal-field the overlying have a greater extension. Under these strata the Coal Measures are succeeded by the Mountain Limestone, and then by Devonian or Silurian strata; but with one or two limited exceptions their outcrop is hidden by the newer strata which stretch uninterruptedly northward over the rest of Belgium. The Palæozoic strata have, however, been met with near Brussels, under Tertiary strata, at a depth of about 600 feet, and at Ostend at a depth of 985 feet, of which 682 consisted of lower Tertiary strata, 210 feet of Chalk, and 93 of coloured marls. It appears, therefore, not improbable, that the Tertiary and Cretaceous strata of all Belgium may repose directly on a floor of Palæozoic rocks; and as there is reason to suppose that all these rocks have a strike parallel with that of the Ardennes, folds in the strata may bring in some under-ground coal-basin or basins in parallel lines to the north, in the same way that small troughs of Coal Measures are brought in again in the Ardennes to the south of the great coal-trough. On the other hand, the great Palæozoic axis of the Ardennes, consisting of Silurian and Devonian rocks, Mountain Limestone, and Coal Measures, passes westward under the Chalk of the north of France, and has been followed under ground as far as Calais, where it lies at a depth of 1,032 feet; while in the direction of Boulogne it keeps nearer the surface, outcrops from beneath the Chalk downs surrounding the Boulonnais, and disappears westward under an unconformable series of Jurassic and Wealden strata.

We may, I think, look for a prolongation of this old Palæozoic surface of highly inclined, contorted, and faulted rocks at no very great depth under the same Wealden, Chalk, and Tertiary area of the south of England. For, although the old Palæozoic surface descends rapidly from about 300 feet above the sea-level in the Boulonnais to 1030 feet below it at Calais, it rises at Ostend 47 higher than at Calais, and crossing the Channel, it is found at Harwich within a few feet of the same depth as at Calais, from which it is eighty miles distant in a northerly direction. Passing westward from Calais, we find the Palæozoic rocks under London 105 miles distant, and 102 feet higher than under Calais, and 106 feet higher than at Harwich. Allowing for irregularities of the old surface as evinced by the well at Crossness, near Plumstead, which was still in the Gault at a depth of 944 feet, or some 14 feet below the level of the Palæozoic rocks at Kentish Town, we may still consider that in the area between these three points, and possibly throughout the south-east of England, the Palæozoic rocks will probably be found not to be more than from 1,000 to 1,200 feet beneath the sea-level.

Projecting the line another 100 miles westward, we reach the neighbourhood of Bath and Frome, where the Coal Measures are, as before mentioned, lost at a depth of about 450 feet, beneath Liassic and Jurassic strata. In the intermediate area between that place and London no trial-pits and no wells have been carried to a depth of anything like 1,000 feet beneath the

sea-level. The deepest well with which I am acquainted is one near Chobham, in Surrey, through Tertiary strata and Chalk to a depth of about 800 feet, or of 550 feet beneath the sea-level.

There are, however, in all this area certain indications of the proximity of old land and of pre-Cretaceous denudation, in the presence of quartz and Lydian pebble-stones, accompanied by Secondary rock fossils in the Lower Greensands of Surrey, and in the like old rock pebbles, with the addition of slate pebbles, in that formation in North Wiltshire; while the banks of shingle, Bryozoa, and sponges of the same age at Farringdon, point to still and sheltered waters, probably of no great depth, and to adjacent dry land. Again, on the north of London, we have in the Lower Greensand of Buckinghamshire and Bedfordshire shingle beds consisting almost entirely of fossils derived from Jurassic strata, with a remarkable collection of larger quartz, quartzite, and other rock-pebbles, derived probably from the old Palæozoic axis.

On the south also of the great Mendip and Ardennes axis coal strata may possibly be found just as they are found on both sides of the Pennine chain; for in either case the measures are cut off and broken through by these chains of hills. In South Wales certain folds of the older strata seem to render it probable that the Coal Measures may pass under the Bristol Channel, forming a trough which prolonged eastward would pass along the south side of the Mendips. Trials in the latter area, have, however, shown that the New Red Sandstone, Lias, and Oolitic series attain an infinitely greater thickness than on the north flank of that range, so that it is not likely that the Coal Measures would lie at a less depth than from 1,500 to 2,000 feet.

On further consideration of the subject, it seems to me a question whether we should not take a still broader view of this great east and west axis, and assign to it a width varying from thirty to eighty miles or more, looking at the Mendips and Exmoor hills as the bounding flexures north and south of the same line of disturbance in South-western England, while the ridges of the Ardennes, the Eifel, and the Hunsrück (in part?) are exhibitions of the same parallel series of anticlinals. In that case the great coal-basins of South Wales and Somerset would represent the synclinal trough on one side of the axis of disturbance, and on the other side we should have the Lower Carboniferous or Coal Measures of Devon; while on the Continent the deep, narrow synclinal trough of the Liège and Aix-la-Chapelle basin may be considered as lying on one side of the arch, and the great coal-basin of Saarbrück on the other. This important coal-basin has already been followed under the New Red Sandstones of the Vosges for a distance of from twenty-four to thirty miles in the direction of Metz, still on the strike of the Ardennes. Further westward, a trial for coal near Doncherry led to the discovery of Palæozoic rocks, at a depth of 1,090 feet under that thickness of Lias and Infra-lias; but the line of the coal-trough should, I think, pass a few miles to the south of this spot. Thence this underground coal-trough would range in an irregular east and west line, keeping parallel, or nearly parallel, with the Mons and Valenciennes troughs, under the north of Champagne, Normandy, the Channel, between the Isle of Wight and Cherbourg, Dorset, and cropping out again in North Devon. The only deep sections that I know of on this line are those furnished by a well sunk many years since, nine miles east of Dieppe, to a depth of 1,092 feet in the Kimmeridge clay and other strata; and another by a boring at Sotteville, near Rouen, through a thin capping of Cretaceous strata, to a depth of 1,050 feet in the same Kimmeridge clay—in either case without reaching the Palæozoic rocks. At Paris no Palæozoic rocks have been reached at a depth of 2,000 feet.

In this country the newer strata, overlying the Palæozoic rocks on our presumed anticlinal line, have been sunk through, without result, in the lowest beds of the Wealden at Hastings to a depth of 486 feet, in the upper beds at Earlswood, near Reigate, to a depth of about 900 feet, and, on the presumed synclinal line of Carboniferous rocks, through Chalk at Chichester, to a depth of 945 feet, and at Southampton, through Tertiary strata and Chalk to a depth of 1,317 feet.

To the south of all the area we have now described, there existed during the Carboniferous period, the ranges of the older Palæozoic strata of the Hunsrück and Vosges—of the old crystalline rocks of Central France, fringed on the east and north with small outlying coal basins of the old Palæozoic rocks of Brittany—and of the Silurian rocks of South Cornwall—forming the old land-surface, fringed by the great coal-growths subtended northwards through Northern France, Western Prussia, Belgium, and

England, to the Silurian uplands of Central Scotland on the north, and those of the Welsh and Cumbrian highlands on the west, and possibly to those of the Scandinavian hills on the north-east. After the formation and consolidation of the Coal-strata, the southern area of this great Carboniferous basin was then subjected to that remarkable disturbance which, for a distance of above 800 miles, exercised that excessive lateral pressure by which the older underlying strata were squeezed and forced up into the series of sharp anticlines forming the axis of the Mendips and Ardennes, while portions only of the Carboniferous series were preserved from the denudation which followed, in deep synclinal troughs flanking the main axis.

The central and northern portions of the great Carboniferous basin, which were not raised by this disturbance, were then over-spread by strata of the Permian series; after which the northern section of the original coal area was traversed by that other great disturbance at nearly right angles to the former one, by which fresh portions of the Coal Measures were brought up in our central and northern counties, still leaving other deeper-seated portions to be afterwards covered by Triassic and Jurassic strata.

At a much later period the emerged southern area of Palæozoic rocks, including the westward prolongation of the great coal-trough of Belgium, or portions thereof, was submerged and covered over by the several formations of the Greensands, Chalk, and Lower Tertiaries now forming the surface of the south east of England.

The trials to discover these possibly productive coal-basins must necessarily be attended with considerable uncertainty. We shall have to feel our way. Of our hope of their ultimate success I have given you the reasons. Nor could such trials near London scarcely fail of some important results; for, even if we did not hit at first upon the Coal Measures, it is probable that the Lower Greensand would at some spots be reached, so that the inestimable additional benefit of a large and steady supply of pure water might also be obtained, and, with proper care to prevent undue interference, might be maintained for all time.

And now, gentlemen, in retreating from the chair, which I have had the honour to occupy during the last two years, allow me to express the sincere satisfaction I have experienced in witnessing the continued prosperity of the Society, and the unanimity and oneness with which its labours are carried on. It was a post I long hesitated to accept, but which your kind forbearance and the friendly co-operation of your officers, has not only rendered easy, but as pleasant as it has been gratifying. I feel assured of the continued prosperity and usefulness of the Society when I resign my trust into the hands of a nobleman so distinguished as a statesman, so able as a writer, and so long known amongst us as an active and zealous geologist, as the Duke of Argyll.

SCIENTIFIC SERIALS

The Lens, a quarterly journal of microscopy and the allied natural sciences, with the Transactions of the State Microscopical Society of Illinois, edited by S. A. Briggs. No. 1, January 1872. Chicago, U.S. This long-promised journal has at length made its appearance, and we learn from its first number that it was printed and ready for the mail when the great fire occurred. With the exception of a few copies, the whole edition was destroyed, and on recovery from that disaster had to be reprinted. We have cause, therefore, to congratulate the publishing committee on recovering themselves so speedily as to issue their first number with the new year. Amongst its contents we note the following:—"Conspectus of the families and genera of the Diatomaceæ," by Prof. H. L. Smith. This is an artificial key, and like all such efforts has its good and bad sides. As a help such guides are useful, but they are seldom satisfactory. A table of synonyms is promised in the next number.—"The Flora of Chicago and its vicinity," by H. H. Babcock, is hardly such a subject as we should expect to find in a microscopical journal, since the list of Phanerogamic plants, with localities, here commenced, contains no single note of microscopical observation. To the local botanist it will probably make amends for this by its practical utility.—"On the preparation and preservation of sections of soft tissues," by Dr. J. N. Danforth, contains practical observations on the preparation of morbid animal tissues without artificial hardening.—"Microscopical Memoranda for the use of Practitioners of Medicine," by Dr. J. J. Woodward, U.S. Army, is the first portion of a more elaborate treatment of the same subject, which is to be contained in succeeding num-

bers. Dr. Woodward's reputation on this side the Atlantic as a practical microscopist is a sufficient guarantee for these memoranda.—"A new fossil Echinus," by O. S. Wescott, is named by the author *Oligoporus Greveri*, and found in the limestone region of Hancock County, Illinois.—"The Diatomaceæ of Lake Michigan," by S. A. Briggs, is simply a list of species.—"A New Method of Illuminating Opaque Objects under high powers," by Dr. H. A. Johnson. This new method consists in sending a beam of light down the oblique body of the binocular upon the prism, by means of a plane mirror or rectangular prism; by this arrangement objectives as high as $\frac{3}{4}$ in. have been used successfully by daylight and lamplight.—"A reprint from the *Monthly Microscopical Journal* and some notes complete the present number. The losses which the Academy of Sciences of Chicago sustained by the late destructive fire are detailed, in so far as the natural history collections and library are concerned. All British naturalists will sympathize with those of Chicago at their irreparable misfortune in such losses as the Smithsonian collection of crustacea, which filled 10,000 jars, and the invertebrates of the U.S. North Pacific Exploring Expedition, besides the thousands of specimens, zoological, botanical, and mineralogical, in the general collection.

Journal of the Chemical Society, Jan. 7, 1872.—Dr. Gladstone has continued his experiments on various essential oils; amongst others he has examined four new oils, those of citron, lign aloes, pimento, and vitivert; the author has separated the hydrocarbons contained in most essential oils into three polymeric groups to which the formulae $C_{10}H_{18}$, $C_{15}H_{24}$, and $C_{20}H_{32}$, have been assigned. The two bodies first mentioned have the vapour density required by theory, the third has not been examined, the three bodies also differ in their solubility in alcohol, and in their expansibility by heat. The physical properties and chemical composition of several oils have been studied in detail, and are here described. Dr. Armstrong contributes a third paper on the nitrochlorophenols, the results obtained, however, are not suitable for useful abstraction. Amongst the abstracts there is one by E. Budde "on the action of light on Chlorine and Bromine." The author has exposed chlorine to the action of various parts of the solar spectrum, he found that when the bulb of gas was exposed to the violet and ultra-violet rays, there was from six to seven times as great expansion as took place in the red and yellow part of the spectrum. An ordinary differential air thermometer and also one charged with carbonic anhydride and ether, placed in the blue and violet parts of the spectrum, showed no increase in temperature. The author is of opinion that the hypothesis which he has advanced in explanation "that the chemically active light actually decomposes the chlorine molecules into chlorine atoms" is not a little supported by the fact that the rays which cause the expansion of chlorine coincide with those which are known to render it chemically active. The author believes that the light causes the separation of the molecules into atoms, and that the isolated atoms combine again with the production of heat, and thus lead to an increase of temperature which would account for the expansion of the gas as observed.

The articles of most general interest in the *Journal of the Franklin Institute* for January are by Mr. F. A. Genth, on the Mineral Resources of North Carolina; and by Mr. G. W. Baird, U.S.N., on the Absorption of Gases by Water, and on the organic matters contained therein. The latter contains a series of experiments on the volume of different gases capable of being dissolved in a unit volume of water, and on the amount of oxygen necessary to oxidise the organic matter contained in the water. The editorial notes contain descriptions of a number of novelties in mechanics and physics.—Mr. J. Farrand Henry continues his series of papers on the Flow of Water in Rivers and Canals, and Mr. J. H. Cooper his article on Belting Facts and Figures.—There is also a report by Mr. W. M. Henderson on some experiments on the explosion of steam-boilers, carried out by a committee of the Franklin Institute at the instance of the engineers of some of the American railways.

The *American Journal of Science and Art* for February is mainly geological. It commences, however, with some observations by Prof. C. A. Young on Encke's comet, at the Dartmouth College Observatory, accompanied by drawings. He identifies the spectrum with that of Comet II. 1868 (Winnecke's comet) described by Mr. Huggins in the *Philosophic Transactions* for that year.—Prof. J. D. Whitney has a note on the occurrence of the "Primordial Fauna" of Nevada, which he considers indicates most unequivocally the Potsdam period of the Silurian age, and carries

the Primordial Fauna much farther west than it had been found before.—Prof. Dana's notice of the address of Prof. T. Sterry Hunt, before the American Association at Indianapolis has already appeared *in extenso* in our columns.—Prof. Roland Irving on the age of the Quartzites, Schists, and Conglomerates of Sauk Co., Wisconsin, holds them to be unquestionably islands in the Potsdam Sea, furnishing beautiful illustrations of wave action on a rocky coast.—Prof. Hayden gives an extremely interesting account, illustrated by maps, of the hot springs and Geysers of the Yellowstone and Firehole Rivers, the result of the recent Government exploration of that district. Prof. T. Sterry Hunt continues his notes on granite rocks, and Mr. A. S. Verrill his contributions to Zoology from the museum of Yale College.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 11.—“Researches on Solar Physics.”—III. By Warren De La Rue, F.R.S., Balfour Stewart, F.R.S., and Benjamin Loewy.

The authors present in this paper the third instalment of the determination of the areas and heliographic positions occupied by the sun-spots observed by the Kew photoheliograph, comprising the years 1867, 1868, and 1869. They announce that the fourth and last instalment is in active progress, and will be preceded by the final discussion of the whole ten-yearly period, during which the photoheliograph has been at work. This final discussion will contain the determination of the astronomical elements of the sun on the basis of photographic observations, and this work they anticipate will not only settle the question of rotation for a considerable time to come, but will also throw light upon many points which have only recently been brought under the consideration of scientific men. The results in general, they believe, will prove the superiority of photographic sun-observations over previous methods. The second question which will be discussed is the distribution of sun-spots over the solar surface. The facts already brought out indicate that the progress of the inquiry may lead to some definite laws which regulate the distribution; there appear to exist centres of great activity on the sun, and the different solar meridians seem to have various but definite intervals of rest and activity. In conclusion the authors point out the necessity of devoting in future greater attention to the study of the facule, and express a hope of seeing photographic sun-observations carried on in this country on a more extended system, connecting from day to day solar phenomena with terrestrial meteorology and magnetism.

Correction to Messrs. De La Rue, Stewart, and Loewy's papers. “On some recent Researches in Solar Physics, &c.”

The erroneous date given in our paper for one of Professor Wolf's maxima has already been corrected by us, and we give in the subjoined little table the corrections of the few numerical data which are necessitated by the error of fixing the date of maximum at 1846.6 instead of 1848.6.

Prof. Wolf's ratio $\frac{A}{B}$ (p. 86).

Erroneous figures given previously.		Corrected figures.	
Differences.		Differences.	
I. 1.265	—0.728	1.265	+0.283
II. 2.615	Mean 2.093 +0.522	1.478	+0.073
III. 2.400	+0.307	1.900	+0.352

The differences derived from our own results are respectively +0.061, and —0.047, that is, they are still much smaller, and agree singly better with the mean, than if Prof. Wolf's ratio were adopted; hence our conclusion is quite unaffected by this correction.

The remark made by us with reference to this maximum will remain in force even with the corrected date. We stated there that this particular maximum showed alone an appreciable difference from the dates fixed by ourselves, for it will be found that Prof. Wolf's date differs still by about three-quarters of a year from ours.

“Contributions to the History of the Opium Alkaloids.”—Part V. By Dr. C. R. A. Wright.

“The Action of Oxygen on Copper Nitrate in a state of Tension.” By Dr. J. H. Gladstone, F.R.S., and Alfred Tribe, F.C.S.

In our experiments on the action between copper and nitrate

of silver in solution, we frequently noticed that the tips of the silver crystals became red, as though coated with a thin layer of metallic copper.

This apparent deposition of a positive on a more negative metal of course raised our curiosity, and led us to look closely into the circumstances under which it occurred. We found that it took place only when the nitrate of silver was exhausted, and only on those silver crystals which remained in metallic connection with the copper. We found, too, that the cupreous coating formed most readily where air had the freest access; and, in fact, that it would not form at all in vessels from which oxygen was excluded, nor on those white crystals which were far below the surface of the liquid, though they might be in immediate contact with the copper plate. When an inverted jar was filled with nitrate of copper solution and silver crystals resting on branches of copper, and the liquid was displaced by oxygen gas, it was found that the tips of the crystals became red, and the solution gradually filled the jar again by the absorption of the gas. In the same way the oxygen was absorbed from air, or from its mixtures with hydrogen or carbonic anhydride. This action was further studied by employing plates of the two metals instead of copper covered with silver crystals. When the two plates, connected by a wire, were partially immersed in an ordinary aqueous solution of copper nitrate, it was found that a slight yellowish deposit made its appearance speedily all over the silver plate, and went on increasing for a day or two, while at the air line there was a thicker deposit, which gradually grew and extended itself a little below the surface. This deposit changed from yellowish to red, and under the microscope presented a distinctly crystalline appearance. Thinking that this slight crust all over the silver plate was due to the air dissolved in the solution itself, we took advantage of the reaction to prepare copper nitrate absolutely free from dissolved oxygen. An ordinary solution of the salt mixed with some silver nitrate was placed in a narrow cylinder, with a long piece of copper foil arranged somewhat spirally so as to retain the deposited silver on its surface, and allowed to rest for twenty-four hours.

The solution thus obtained was exposed to the action of the conjoined copper and silver plates, but even after some hours there was no diminishing of the lustre of the silver plates, except at the air line, which was sharply defined. The same solution shaken for some time in the air produced a yellowish deposit on the white metal in three minutes.

The colour and general appearance of this crust, together with its formation only where oxygen can be absorbed, showed that it was not metallic copper, but the suboxide.

This was further proved by the action of diluted sulphuric acid, which resolves it at once into red metallic copper and copper sulphate. There is also another curious reaction which can only be properly observed under a microscope.

When treated with a solution of silver nitrate, this cupreous deposit does not give the ordinary crystals of the white metal; in fact, it is only slowly acted upon, but presently there shoot forth thin threads of silver which run through the liquid, often twisting at sharp angles, while the yellowish crystals change to black. This also was found to be a property of the suboxide of copper. This deposition of oxide on the silver is accompanied by a corresponding solution of copper from the other plate.

Thus, in an experiment made with nitrate of copper solution that had been exposed to air, and which was allowed to continue for four days, there was found—

Gain of silver plate, 0.016 gm.
Loss of copper plate, 0.015 gm.

The copper necessary for the production of 0.016 gm. of suboxide would be a little above 0.014 gm.

The wire connecting the two plates in this experiment is capable of deflecting a galvanometer. The current takes place from copper through the liquid to silver, that is, in the same direction as if the copper had been dissolved by an acid, and hydrogen evolved on the silver plate.

If the two plates have their sides parallel, the suboxide is deposited not merely on that side of the silver plate which faces the copper, but after about a minute on the other side also, showing that in this, as in other cases, the lines of force curve round.

It became interesting to consider what started this electric current. The original observations convinced us that it was not due to the action of oxygen on the copper; but to make the matter more certain, bright copper and silver plates in conjunc-

tion were immersed, the copper in a pure, *i.e.* deoxygenised, solution of nitrate of copper, the silver in an oxygenised solution; the two liquids communicated through the diaphragm of a divided cell. In half an hour the silver plate was covered with a reddish film, while not a trace of oxidation was perceptible on the copper. On continuing this experiment for three hours, it was found that the copper plate lost 0.003 grm., and the silver plate increased proportionately. On cleaning the plates and reversing their position, the copper was covered with a film of oxide, while the silver remained free from cupreous deposit. We believe, therefore, that through the simultaneous action of the two metals the dissolved salt is put into such a state of tension that oxygen brings about a chemical change which otherwise would be impossible, and that this change is initiated in close proximity to the more negative metal.

Though we have examined only this reaction, we have satisfied ourselves that it is not an isolated fact. Each of the elements concerned may be replaced by others: thus the sulphate may be substituted for the nitrate of copper, or platinum may be used instead of silver. Chlorine may take the place of oxygen with the production of the subchloride instead of the suboxide, and zinc may be employed as the positive metal with zinc chloride as the salt in solution, in which case copper may be taken as the negative metal, and on its surface will form a deposit of oxide of zinc.

Linnean Society, March 21 and April 4.—Mr. Bentham read the continuation and conclusion of his notes on Composite, comprising their History and Geographical Distribution. The ancient history of the order is more purely conjectural than that of many other large groups of plants. The geological record is remarkably scanty. The only remains that can be plausibly referred to Composite are the impressions of achenes with their pappus figured by Oswald Heer from the upper Miocene deposits of central Europe, which, supposing, as is probably the case, that the identifications are correct, would only show that at that tertiary epoch Composite existed in Europe of the same general character as those which are there now to be met with; and that they had thus already attained that highly differentiated character they now possess, and consequently must already have been of an old date. In the absence, therefore, of direct evidence, we are left to judge of the antiquity and origin of Composite in general, as well as of the subordinate races they comprise, from their comparative structure and geographical distribution. The paper then proceeds to pass in review in great detail the thirteen tribes of Composite, and the several subtribes and principal genera into which they are divided; after which some conjectures are put forward, as derived from the data thus supplied, as to the comparative antiquity of the principal races of Composite. Concurring with the arguments which have been brought forward by French and other botanists, to show that the great consolidation and uniform structure of the essential organs of fructification in Composite are evidences of their greatest perfection and consequent comparatively recent origin, it is shown that this consolidation and uniformity is least marked in Helianthoidæ, especially in the small subtribe of Petrobiæ, and most so in Cichoraceæ; and this conjecture that the former represent the most ancient, the latter the most recent, races of the order, is confirmed in some measure by the peculiarities of their respective geographical distribution. The study of the various details given would further lead to the supposition that the primitive form of Composite had regular gamopetalous flowers with an inferior ovary, the calyx, corolla and uniseriate stamens isomerous and probably pentamerous, the pistil bicarpellary, but the ovary already internally reduced to a single cell with a single erect anatropous ovule, and the seed exalbuminous, enclosed in an indehiscent pericarp, and containing a straight embryo with an inferior radicle; and that it is in the gradual course of subsequent consolidations that the bracts have crowded round the condensed flowers and usurped the functions of the calyx-limb, which has become obliterated or transformed so as to be better adapted to its new duties; the corollas have become contracted, or the outer ones variously developed in forms and colours adapted to assist in the process of cross-fertilisation; the anthers, brought into close contact by the compression of the flowers, have become united, and their styles modified so as to assist them in the discharge of their pollen, and the conversion from hermaphroditism to unisexuality may in various races have variously preceded or followed some or all of these changes, and produced those numerous diversities

observed in the order. We might be further led to imagine that several of these changes had taken place at a very early period previously to the disruption or stoppage of communication between the tropical regions of the globe, that, besides the parent forms above supposed to be represented in some Helianthoidæ, and perhaps a few Crotulæ, Composite then existed, showing several important modifications, such as—(1) the regular and uniform tubular development of the corolla, accompanied by more or less of suppression of the inner bracts, and of the normal calyx-limb, with a substitution of a pappus in the latter case; (2) the reduction of the corolla limb, attended frequently by a sexual dimorphism and occasional oblique development of the outer female flower; and (3) perhaps at a later period, the uniform unilateral development of the whole of the corollas, accompanied usually by a suppression of the inner bracts and conversion of the calyx limb into a pappus. From the first of these modifications would have sprung the Eupatoriaceæ in America, the Vernoniaceæ in the New and the Old World, the Cynroideæ in the northern, and the Mutisiaceæ in the southern hemisphere. From the second modification would have arisen—first, the more slightly altered Helianthoidæ chiefly in America; secondly, the Helmioidæ in America, and the Anthemideæ in the Old World, with the thinly paleaceous modification or total suppression of the inner bracts and calyx limb; and thirdly, the cosmopolitan Senecionideæ, Asteroidæ, and the majority of Inuloidæ, with an almost universal suppression of the inner bracts and conversion of the calyx limb into a setose pappus. The third general modification, with a very few slight exceptions, has settled down into those Cichoraceæ whose absolute uniformity had been already pointed out. In the third and concluding portion of the paper the present Regions, or chief centres, or areas, of the principal races of Composite are passed in review. The position of these great centres is evidently influenced by the prevalent constitution of the order, and the consequent effects of climatological and other physical causes on the gradual migrations of its species. Rarely arborescent and gregarious, still more rarely aquatic, Composite are, in a great measure, excluded from the vast forest-clad lowlands of the Amazon region of America, or of eastern tropical Asia, and the species are few in the swampy bogs of the northern hemisphere. Their favourite haunts are treeless or thinly-clad mountain regions, and especially the lower or broken grounds, rocky ridges, or open campos of warm extratropical or subtropical districts. They may be met with, it is true, at the highest altitudes or latitudes which will bear phenogamic vegetation as well as in the warmest tropical deserts, and a few species, as ready colonists, are perfectly ubiquitous in the traces of man; but there are large tracts of open country especially abounding in highly differentiated races of very limited areas, others again where Composite genera and species are as numerous and ill-defined in their subordinate races as wide and vague in their geographical range. These tracts of country severally constitute the centres of differentiation or areas of preservation, of which the definition is attempted as Regions of Composite. After alluding to the difficulties arising from the interchange of races across the frontiers of adjoining regions, or from the occasional reappearance of identical genera and species at enormous distances, as well as from our imperfect acquaintance with the Composite of certain districts, these regions are severally passed in review, in a series of tables of the genera they contain, either endemic or common to other regions, followed by such general observations as the comparisons may have suggested, commencing with the primary division into the New and the Old World, the former including the Sandwich as well as the more nearly placed Pacific Islands, whilst the Atlantic islands, Australia and New Zealand, are comprised in the Old World. After a general table of the genera of and estimated number of species in each division, a series of tables shows—(1) the connections between the tropical regions of the two divisions, as exemplified by identical genera; (2) the same connections in identical species; (3) the northern, and (4) the southern connections of the New and Old Worlds. Generally Composite are nearly equally divided between the two, about 430 genera in the New and 410 in the Old, with at least 4,700 species in the former, 4,400 in the latter; new discoveries being likely to add more to the latter. Of these numbers about 75 genera are common to the two divisions, but the identical species are under 70 out of at least 9,100. These common species are chiefly Arctic, or high northern, the tropical ones being very few and mostly very generally diffused, and ready colonists, such as *Eclipta alba*, *Ageratum conyzoides*, *Adenostemma viscosum*, *Sisymbrium officinalis*.

In the separate distribution of Compositæ in America and the Old World there is one striking difference in the two divisions with regard to the extratropical or subtropical races which form the great bulk of the order. In America the northern and southern tribes are the same, although in different proportions, and there are a considerable number of identical genera and even species in the north and in the south. In the Old World on the contrary two large northern tribes, Cynaroideæ and Eichoroceæ, are all but absent from the south, whilst the southern Aretoidæ, as well as several subtribes of other tribes, are wanting in the north. The genera common to the Mediterranean and South African regions (except such cosmopolitan genera as *Senecio*) are very few, and the common species scarcely any. This great difference in the two divisions of the globe may be due in a great measure to the direction of the great chain of mountains which in America, running north and south, facilitates or has facilitated means of intercommunication to races of the constitution of Compositæ, to which the east and west mountain ranges plains seas and deserts of the Old World only oppose obstacles. The regions of which the Compositæ are severally tabulated and commented upon are, in America: (1) the Mexican region including California, a portion of Western Texas and Central America north of Veraguas, remarkable for the large number of endemic genera, 135 out of 240, and the small average number of species; (2) the United States region, comprising the general area of North America from the Oregon and Texas eastward and northward, with about 118 genera, out of which only 25 are endemic, or nearly so, but the average number of species more than double that of the Mexican genera; (3) the West Indian region, of which the three principal islands, Cuba, St. Domingo, and Jamaica, have 13 endemic genera of one to three species each; and three South American regions, the Andine, the Brazilian, and the Chilian, not so distinct from each other, nor showing any such remarkable contrasts as the two northern ones. In the Old World six regions are distinguished—(1) the Mediterranean, extending from Spain to Afghanistan, with at least 140 genera, more than half of them endemic, and an average of nearly 10 species to a genus; (2) the great Euræo-Asiatic region, extending from Western Europe to Eastern Asia, with a large number of species, but only 10 endemic genera out of 87; (3) the Tropical African, with 18 endemic genera out of 99; (4) the Tropical Asiatic, with only 9 out of 78 endemic or nearly so; (5) the South African, the smallest in extent but the richest in endemic highly differentiated genera and species, 100 out of 148 genera being limited to that locality, and out of about 1,400 species not above a dozen common to other regions; and, lastly, (6) the Australian region, with 39 out of 83 genera endemic, and, notwithstanding its isolation, nearly 60 species common to other countries, chiefly tropical Asia and New Zealand. The Compositæ of the principal Oceanic islands are also separately tabulated and considered; after which, in the general summary, it is conjectured that Africa, Western America, and possibly Australia may have possessed the order at the earliest recognisable stage, Africa showing the greatest variety of individual isolated remnants of extinct races; Andine America, and some of the scattered Oceanic islands, exhibiting a few of what may be deemed the nearest approach to the previously mentioned conjectural primitive form of the order; that at this early period there must have been some means of reciprocal interchange of races between these regions; that since the disruption of this intercourse between the two great divisions of the globe, there must have been for a time a certain continuity of composite races from north to south across the tropics—a continuity which was probably further prolonged in America than in the Old World; that as Compositæ which thenceforth opposed to them impassable barriers, they became rapidly differentiated to the northward and southward, with greater structural divergences in the Old than in the New World, owing to the isolation being more complete in the former than in the latter; and that those forms, those more or less differentiated races, which had reached and accommodated themselves to high northern latitudes or mountain altitudes, retained some means of communication and interchange between the Old and the New World, long after it was broken off in the warmer parts of the globe. Finally the homes where Compositæ now flourish in the greatest luxuriance of specific variety and individual numbers, appear to be tropical America, exclusive of the great alluvial low grounds and forest regions, the United States, South Africa, the Mediterranean region, West Central Asia, and extra-tropical Australia.

Geologists' Association, April 7.—The Rev. J. Willshire, F.G.S., president, in the chair. "On the Excavations at the Site of the New Law Courts," by W. H. Hudleston, F.G.S., and F. G. II. Price. The authors commenced with a general description of the area in question, which faces the Strand for 500 feet, and is in shape a rough square of some seven acres in extent. The floor of the excavation is about 33 feet above ordnance datum line at the south-east corner. Four varieties of beds are recognised. (1) Brick rubbish, &c.; (2) gravels and sands; (3) red clay; (4) blue clay. The nature of the changes which the London clay undergoes in its upper portions was noticed, and the chemical agencies acting upon the clay and its included septaria pointed out. The changes from blue to red were thus summarised:—Conversion of dyad iron, existing partly as carbonate partly as a basic element of the silicate, into triad iron, oxidation of the included pyrites, removal to a considerable extent of the resulting sulphuric acid and diminution of the carbonate of lime and magnesia. The several sections carefully examined by the authors showed that on the north side the gravels have a thickness varying from 9 to 13 feet, and thin out and disappear before the Strand is reached. The contour of the London clay is irregular, one line of 30 yards giving a variation of 7 feet in the thickness of the overlying gravels, due to this cause. Deposits of oxide of manganese and sulphide of iron occur in the gravels; the former, it was contended, due to natural causes, while the latter was probably owing to sewage contamination. The bones of *Bos*, *Capra*, and *Equus*, were found in the gravels, and in the underlying clay twenty-three species of mollusca, including *Fusus bifasciatus* and *Pyrula smithii*, characteristic, in the opinion of Mr. C. Evans, of a line of the London clay 130 feet above the base. The gravels belong to the west London block of the Middle Level gravels, the ascertained thickness of which at various points was compared with the thickness of the Lower Level gravels at South Kensington, Battersea, and Westminster. These latter the authors concluded were double the thickness of the western block of the Middle Level gravels. In conclusion the authors drew attention to the results of the operations of the existing river, and several accurate measurements of the bed of the Thames were given in illustration.—Mr. E. Charlesworth brought before the notice of the Association some sharks' teeth from the Red Crag, having certain perforations which, should they be proved to be the result of human agency, would seem to carry the advent of man on the earth back to Pliocene times.

Society of Biblical Archaeology, April 2.—Dr. Birch, F.S.A., president, in the chair. "Notice of a Curious Myth respecting the Birth of Sargina, from the Assyrian Tablets containing an account of his Life," by Henry Fox Talbot. In this paper Mr. Talbot showed that Sargina the First was a very ancient king of Babylonia. The date of his reign is uncertain, but it may be roughly estimated at fourteen or fifteen centuries before the Christian era. He was a legislator and a conqueror, and his arms appear to have reached the distant Mediterranean. He fixed his capital at Agani, in Babylonia, a city whose site has not yet been discovered. His history, like that of other ancient conquerors and legislators, has become partially involved in fable. An account of his birth and infancy, preserved on a tablet in the British Museum, offers a great similarity to that of the infancy of Moses, as related in the second chapter of Exodus. This account agrees very closely with the conduct of Sargina's mother as described by the Assyrian tablet. "In a secret place my mother had brought me forth. She placed me in an ark of bulrushes; with bitumen she closed up the door. She threw me into the river, which did not enter into the ark. The river bore me up, and brought me to the dwelling of a kind-hearted fisherman. He saved my life, and brought me up as his own son," &c. The inscription appears to have been a long one, but only a small portion of the beginning has been well preserved.—"On the Rise of Semitic Civilisation, chiefly considered upon Philological Evidence," by the Rev. A. H. Sayce. The author stated that comparative grammar has shown that the Semitic language belongs to a late period in the history of the development of speech, and presupposes a parent-language, possibly connected with the old Egyptian and the sub-Semitic dialects of North Africa. Many objections, however, lie against the biliteral theory, and most of the biliteral roots are probably of foreign origin. This is Accadian, also the source, it would seem, of the early Semitic traditions. Thus two at least of the rivers of Paradise are Babylonian, and the Sisuthrus

of Berosus (the Biblical Noah), is the Accadian Susru or Na (Anu). Like the traditions, a large proportion of the words in the Semitic languages which express the objects of civilised life are borrowed from the Accadian—the ordinary terms for “city,” “weighing,” “measures,” “ciphers,” &c., come from this source. We are thus enabled to gauge the primitive civilisation of the Semitic nomads, and to determine that their home had no great rivers or mountains, like the deserts of Northern Arabia.

PARIS

Academy of Sciences, April 1.—M. Serret presented a continuation of M. A. Mannheim's geometrical researches upon the contact of the third order of two surfaces.—A paper was read by M. C. Decharme on the spontaneous ascensional movement of liquids in capillary tubes. The author here stated as the result of his experiments that each liquid possesses a proper ascensional velocity, which he proposes to call its “capillary velocity,” and he indicated the peculiarities presented by certain liquids as regards the relation between this velocity and the length of the column, &c. An aqueous solution of hydrochlorate of ammonia has the greatest capillary velocity, and next to it chloride of lithium; both these have a greater velocity than pure water.—A note by M. de la Rive on the theory of polar auroras was read; the author maintains the atmospheric nature of the phenomenon.—The second part of a paper by M. A. Crova on the phenomena of interference produced by parallel nets was read.—M. Faye gave a long account of an association recently founded in Italy under the title of “Società dei Spettroscopisti Italiana,” and also presented a memoir on the hypothesis of persistent winds on the sun.—In a second communication on the history of fermentation, M. E. Chevreul described in some detail the chemical labours of Stahl, and especially his theories of fermentation and combustion, which the author regarded as physical rather than chemical.—M. Joseph Boussingault presented a note on sorbite, a saccharine material allied to mannite, obtained from the juice of the berries of *Sorbus aucuparia*.—A note was read by M. A. Clermont, on some metallic trichloracetates, and M. Balard presented a note by M. E. Reiboul on the identity of the brominated hydrobromate and hydrodate of propylene, with dihydrobromate and iodo-hydrobromate of allylene, and on the dihydrobromate of acetylene.—A note by M. Duval-Jouve, on the anatomy of the disseminates presented by the leaves of certain species of *Juncus*, was communicated by M. Duchartre.

April 8.—M. Serret presented a note by M. E. Combescure on a peculiar system of equations with partial differences; and a paper entitled “Investigations upon substitutions,” by M. C. Jordan, was read.—M. Le Verrier communicated two notes by M. D. Amilla-Müller, one on terrestrial magnetism, the other on the cosmical origin of auroras. In the latter he claimed priority in having put forward the notion of these phenomena being due to solar influences.—M. J. Silbermann read a continuation of his memoir on the laws of atmospheric tides; and M. C. Sainte-Claire Deville communicated a note by M. O. Silvestri, giving a chemical and microscopic analysis of the sand-shower which fell in Sicily on March 9, 10, and 11 in the present year.—M. Chevreul read a second note on the crystallisation of barytic salts, the acids of which originate from the maceration of dead bodies.—A memoir on the alteration of the sulphurous waters of Eau-Bonne in contact with a limited atmosphere, by the late M. Louis Martin, was read.—M. H. Sainte-Claire Deville presented notes by M. A. Ditté on the apparent volatilisation of selenium and tellurium, and on the dissociation of their hydrogenated compounds; by M. B. Renuat, on the reducing properties of hydrogen and vapours of phosphorus, and on their application to the reproduction of drawings; by M. de Tommassi, on a compound of binoxide of chrome and potassic dichromate, kalichromic dichromate [$(\text{CrO}_3)_2 (\text{CrO}_3)_2 \text{K}_2\text{O}$] H_2O ; and by M. L. Grandjean, on the function of the organic materials of the soil in the nutrition of plants.—M. Cahours presented a note by MM. S. Cléoz and E. Guigret on the chemical composition of the Chinese green (lobbe).—An interesting note on the polymorphism of *Muscovite*, by MM. P. Van Tieghem and G. Le Meunier, was communicated by M. Decaisne.—M. A. Vulpian read a memoir on the alteration of the muscles produced under the influence of traumatic or analogous lesions of the nerves, and on the trophical action of the nervous centres upon the muscular tissue; and M. Gauthier de Claubry presented some observations on M. Champouillon's recent remarks as to the rapid decomposition of the bodies of alcoholised subjects. He adduces facts which seem to show that the difference in the rate

of putrefaction may be, otherwise accounted for.—M. A. de Lapparent read a note on the date of the elevation of the district of Bray.

A PHYSICAL OBSERVATORY

AT the last meeting of the Astronomical Society, a paper was read by Lieut.-Colonel Strange on "The Insufficiency of existing National Observatories." The title is perhaps suggestive of an attack on Greenwich, but this idea the paper at once dispels, the Royal Observatory, and the administration of its eminent director, being spoken of throughout in terms of the strongest approval, in which all astronomers must join.

The aim of the writer was to show that, though Greenwich provides most efficiently and amply for the elder Astronomy, it is now time for us to consider whether her younger sister should not also be permanently provided for. When Greenwich was founded the Physics of Astronomy, which now attract so much attention, had no existence. This department of science is entirely of modern growth; but it has already attained such wide proportions and so deep a significance that it cannot any longer with propriety be left to the chance cultivation of individual zeal. In putting forward these ideas, Colonel Strange has only given expression to what has been for some time in the thoughts of every one interested in astronomy and its correlated sciences. He is right in pointing out to the Astronomical Society that in this direction its influence can and ought now to be exerted. And he gives two very cogent reasons why this should be done at once. First, that the system of photolithography, which has for some years been carried on at Kew by the zeal of individuals, and partly maintained by private means, has now been brought to a close. Second, that the Royal Commission on Science being now at work on the question of the advancement of science, the present opportunity is very favourable for bringing this matter forcibly before Government through that body—an opportunity which will probably not recur in a generation.

The discussion on the paper, as might be expected, was prolonged and animated. The Astronomer Royal, who spoke several times, was doubtful whether the object for which such an observatory was sought to be founded was sufficiently "secular" to ensure success; but on its being urged with great force and truth by Mr. De La Rue and Captain Toynbee—both connected officially with the Meteorological Office—that the study of the sun, as had been insisted on by Colonel Strange in his paper, must greatly aid meteorological research, Mr. Airy candidly admitted that if that pretension can be made good, there will exist a claim on behalf of Meteorology for the establishment of a Physical Observatory, similar to, and as "secular" as, that on behalf of Navigation on which Greenwich was founded.

It is certainly a little disheartening to find a great leader in science insisting so much on direct utilitarianism as the sole basis of national science, and withholding his testimony to the enormous moral and intellectual benefits of philosophical research, and even omitting all consideration of the indirect material results which have invariably followed vigorous and systematic study of natural phenomena of whatever kind. The average Englishman is prone enough to hug what in his untaught stupidity he

calls "practical ideas," and will not be improved by being told by one of the first of living philosophers that such ideas are the standard by which he should measure every proposal for advancement. But it is impossible to suppose that these are the ideas which the Astronomer Royal will on mature reflection apply to the question before us, when deliberately presented to him with a view to action.

It is to be hoped, indeed, that the late discussion will be followed by action. Our Royal Astronomical Society should be the acknowledged head of modern astronomical activity. It has higher functions to perform than those on which its energies have been rather too exclusively exercised—the reading, discussing, and publishing of detached dissertations. It should from time to time take stock of the territory it occupies, in order to see what encroachments need fencing off and what expansions are required. And, above all, it should constitute itself more than it does the guide and encouraging counsellor of the Government in matters which it must understand better than they. We hope to see it awake to its moral obligations in regard to the most important matter which has been so opportunely submitted to it. We do not hesitate to say that if by its interposition a well-equipped Observatory for Physical purposes should be established, this will be the greatest service it will have ever conferred on Astronomy, and not on Astronomy only, but on a vast sphere of scientific inquiry, not obviously, but still indisputably, connected therewith.

In Meteorology such an observatory would ultimately, if not immediately, create a revolution. Instead of the dreary columns of thermometer readings piled upon us by well-meaning but aimless industry, we shall see men of thought labouring to refer to the great source of all energy, the great maintainer of all harmony, the great exciter of all variation—to the sun itself—those phenomena, at present the most difficult in the universe to interpret, which hitherto it has been assumed that any one with 5*l.* to spend on "a complete set of meteorological instruments" can help to elucidate.

Should the want now spoken of be made apparent to those who can supply it, there will be several important preliminary questions to deal with, such as (1) What should be the scope of such an observatory? (2) Should it be engrafted on Greenwich, or be independent? (3) Should Meteorology and Magnetism be engrafted on it and severed from existing connections? (4) Should a system of sun observations—the primary, though, of course, not the sole object of such an observatory—be extended to India and other British possessions, so as to ensure that continuity of facts on which Messrs. De La Rue, Balfour Stewart, and Loewy have laid so much stress in their striking memoirs on Solar Physics recently communicated to the Royal Society?

LANKESTER'S PHYSIOLOGY

Practical Physiology; being a School Manual of Health, &c. By Edwin Lankester, M.D., LL.D., F.R.S. Fifth Edition. Pp. 152. (London: Hardwicke, 1872.)

THE new title adopted by Dr. Lankester for this little work is somewhat misleading. It has nothing to do with Practical or Experimental Physiology, the sub-

ject on which interest has lately so much revived in this country, and on which we hope before long to see a treatise by competent hands. Nor would it be fair to compare this "School Manual" with the admirable "Lessons in Elementary Physiology" of Prof. Huxley. The latter, though intended for boys' and girls' schools, is only of use in the few instances in which dissection and microscopic anatomy are taught; and its chief value is for University men who do not specially take up Biology, and as the best introduction to the subject for medical students. But Dr. Lankester addresses the wider circle of the general public. He shows in the Introduction how an elementary knowledge of the functions of the body and of the rules of health may be taught in primary schools; and proceeds to demonstrate the advantage of this knowledge to statesmen, clergymen, lawyers, architects, newspaper writers, common councilmen, and artisans. Perhaps the most important part of this introduction is that in which the author urges the importance of some knowledge of what is necessary to health for women in all stations of life. A skilful teacher would be able to teach girls of average intelligence a large part, and that the most valuable, of the contents of this Manual. They would probably learn it more readily than boys, and when all memory of the tissues and their names had passed away, it may be hoped that the dogmatic injunctions and prohibitions on food and air and drains and clothing would, at least in part, survive.

The first chapter contains a fair sketch of the constituents of the human body; the second deals with food, and gives sensible advice on many points; but here there are marks of imperfect adaptation of Liebig's theories to more recent facts. The third chapter, on Digestion, is also clear and practical. The next on the Circulation is too technical for the purpose of the book, and might, we think, be relieved of many anatomical terms. The two which follow on Respiration and the Skin, are chiefly sanitary, and might be read with advantage even by those ignorant of physiology. In the seventh chapter, on Movement, Dr. Lankester gives a very uncertain sound on the subject of boat-racing (pp. 76 and 77), in the former passage going so far as to assert that "in all gymnastic exercises competition in feats of strength should be avoided." The public have been already frightened as much as they are likely to be by certain letters on the dangers of boat-racing, which appear at intervals in the *Times* newspaper. It may be said of this, as of other athletic sports, that when competition is avoided gymnastics will cease to be practised. It is surely better to attempt wisely to regulate these contests than to condemn what are just as valuable or as injurious as competitive examinations in mental athletics.

The last two chapters of this manual, which deal with the difficult subjects of the nervous system and the senses, are pleasantly written, and give much useful information; but there are more errors here than in the rest of the book. Thus the discussion of nerve fibres is made to take place in the *corpus callosum*, the arachnoid is described as a "spongy membrane," and the pathology and causes of apoplexy given on the same page are not correct. Again, the physical cause of short sight is not the cornea being too rounded, but the whole eyeball being too long, and if the reader "looks into a living human

eye, through the pupil," as directed in p. 104, he will be disappointed of the promised result. In these as in other particulars the work would have been better if the writer had taken more pains. Beside a number of curious misprints, there are several minor inaccuracies scattered through the book, which a competent physiologist would correct in looking through it. Only two lines of poetry from Shakespeare and Milton occur, and both are misquoted. Similar inaccuracies are to be found in the classification of the animal kingdom printed at the end of the volume, with which it appears to have no very close connection. The glossary, on the other hand, and the questions for examination, will probably be found of practical use. The tables of the ultimate and proximate constituents of the body, also given in the Appendix, are too exact to be correct, and the same may be said of that showing the daily supply and waste. Moreover, 12lb. of fat would make but a meagre man; and 31oz. of water is more than there is reason to suppose that the lungs excrete. The woodcuts which have been added to the present edition are taken from well-known, chiefly French, sources; they are roughly reproduced, but answer their purpose well enough.

In a future edition, which we hope will be called for, it would be well to restore the original title of the work, and correct some of the inaccuracies we have referred to. It might also be desirable to give fuller directions on the choice and preparation of food, and especially of the food suitable for infants and invalids. A chapter on the general management of a sick-room as to warming, ventilation (now often carried to injurious excess), feeding, disinfection, &c., would also be a valuable addition. A short and admirable pamphlet, issued a short time ago by Dr. Bridges ("A Catechism of Health, adapted for Primary Schools," 1870), contains just those points of sanitary knowledge which are most important, and Dr. Lankester's experience as a coroner would be of great service (as it has already been) in enabling him to enlarge upon these most pressing topics, and to illustrate them by well-chosen examples. P. S.

OUR BOOK SHELF

Jahrbuch der kaiserlich-königlichen geologischen Reichsanstalt, xxi. Band. Nro. 4; October, November, December. (Vienna, 1871.)

DR. NEUMAYR occupies the greater portion of this number of the "Jahrbuch" with the third part of his elaborate "Jurastudien." In this paper he describes what he calls "der penninische Klippenzug," a name derived from Penninberge, near Szczawica, on the borders of Western Galicia and Hungary. The structure of this region is treated of at considerable extent. A long list of some two hundred and fifty papers, notices, &c., accompanies the memoir. Herr Franz Toula gives some account of the Randegebirges, near Karlsburg and Rodaun; and the work done in the Chemical Laboratory of the Institute is described by Karl Ritter v. Hauer. The mineralogical communications which accompany the "Jahrbuch" contain, amongst other papers, one by C. W. C. Fuchs, on the mechanical and chemical changes which lava undergoes in passing from the fluid to the solid state; and another by G. Tschermak on the problems of mineralogical chemistry. We have also descriptions of various minerals by Prof. Zirkel, Victor v. Lang, and Richard v. Drasche, and a number of miscellaneous "notices."

The Higher Ministry of Nature: viewed in the Light of Modern Science, and as an Aid to Advanced Christian Philosophy. By John R. Leifchild. (London: Hodder and Stoughton, 1872.)

MR. LEIFCHILD is already known as a careful writer on matters connected with economic geology; he now appears before the public in the avowed character of ambassador between the opposing forces of Theology and Science. This bulky volume of upwards of 500 pages appears to be a kind of commonplace-book of thoughts which have occurred to him in solitary wanderings; the title means to express that the author concerns himself with subjects higher than those which "subserve our present individual and collective interests." We must acknowledge that works of this kind, endeavouring to reconcile in detail the conflicting theories of theologians and men of science, are little to our taste; we suppose, however, they have their public; and in the case of the volume before us, the large type, wide margins, and handsome binding, are all in its favour. With this preliminary objection, that portion of Mr. Leifchild's work which comes within our scope—for the greater part does not—seems treated with considerable care and knowledge, and with a higher degree of impartiality than is usually to be met with in such works. The Darwinian doctrines of evolution and natural selection of course come in for some severe criticism; we are surprised that Mr. Leifchild should reiterate the superficial and often refuted objection that geology has not yet revealed a single fossil *in transitu* from one species to another, as if it were possible that geology should reveal anything but the successive connecting and connected links, which it has done, and is doing every day. Those who delight in speculations on the border-land between the natural and the supernatural will find much to interest them in the volume, and to such we commend it.

LETTERS TO THE EDITOR

Spectroscopic Nomenclature

YOUR columns were not long since opened to a discussion, rather long drawn out, on a point of nomenclature. They are now, as ever, open to all reasonable discussion on that most interesting aspect of Nature presented by the spectroscope. I cannot help thinking that some advance might be made if the facilities exhibited in the one were now brought to bear on the other. There seems to be a lamentable tendency in zealous but disorderly minds to pay as little attention as possible to those aids to reasoning—those signs of ideas, which ought to be current coin.

I do not in the least propose to myself to attempt to mount the breach just now. But I would fain challenge attention, and urge a fair amount of consideration, on some few points in which I have noticed very diverse methods of expressing the same thing. And in so doing I may find it necessary to give my voice in favour of one or the other. But it is not my object to advocate so much as to indicate.

Observations have recently been made of the sun during eclipse of a kind which, if not so novel as some think, is intensely interesting, and must be constantly referred to. I mean with a free prism. Now it occurs to me that it would be easy to reserve the spectroscope for that instrument which we have been accustomed to call such and to characterise these other observations as *prismatic*, as distinct from *spectroscopic*. It would then be known at the very outset that there was no slit. This would not prevent a juvenile disciple of Newton from repeating his prismatic examination of a chink, and getting his linear spectrum; it would only keep before him the origin and constitution of that spectrum in a way which the sole use of the spectroscope appears not to do. The prismatic and the spectroscopic methods of examining a luminous object are totally distinct. Thus the Poodcottah observations were of one kind, those at Dodabetta of the

other; those at Bekul, of both. It is of no consequence, for this matter, where the prism is, it is the absence of the slit that makes the difference. Thus, for the purpose of illustration, I may allude to the planetary nebula seen *prismatically* unaffected in the midst of a star cluster turned into streaks. And the prominences seen in an open slit are to all intents seen *prismatically*. It is obvious that there is here a distinction of idea which may be advantageously fixed by a distinctive use of words. Let the spectroscopic mind its own business, which is to make and examine linear spectra. The moment it ceases to do so it ceases to be a spectroscope.

This brings me to the next point. Since the prism does not require a slit,—on the contrary, is a very valuable tool, as we have seen, without,—it ought never to see *lines*, except as it sees other forms, *i.e.*, out lines. There is a confusion of ideas—rather, I should say, a contraction of ideas—in setting a prism to look for lines. It is the spectroscope which sees lines, the prism sees images, forms. It is an accident of the case if the form happens in any of its parts to be at the same time linear, and having its linear portion in a certain direction. Thus, when in a prismatic examination of the solar crescent immediately before eclipse, the cusps become linear—albeit curvilinear—there is a failure of grasp in speaking of the dark cusp-images as dark lines; or, at any rate, there is an opportunity lost of exemplifying the principle which pervades the whole of the phenomenon, and of fixing the prismatic idea.

The same kind of misuse of terms I have had occasion to point out on the occasion of the first prismatic examination of an eclipse, when what are now called, happily, zones, were unhappily and mistakenly called by the technical term "bands."

I now pass on to the confusion which exists in the nomenclature of lines. The subject fully treated would embrace the whole range of spectral analysis; but I must confine what I have to say to solar spectra.

In the early days of solar examination with the spectroscope, I made my venture, in the direction which I am now pursuing, and it failed. Ignorant that I was already distanced—no matter how or why—I suggested certain symbols for certain lines, foreseeing somewhat of what has come to pass. Aiming to avoid an affiliation which further knowledge might prove false, but admitting the great probability that the lines at C, F, 2796 (K) were really due to hydrogen, I would have called these solar bright lines α, β, γ , the hydrogen lines being already known as H α , H β , H γ ; that which is now variously called "D $_2$," "D $_3$," "near D," or sometimes plain "D," I would have had known, in the same category, as δ . And other Greek letters expressed, and would have sufficed to express, as many more as the memory would require to hold. The venture failed, as I say; and considering that no little confusion has resulted, I cannot help thinking it a pity that it did. Soon after appeared a work on spectrum analysis, in which H γ is ignored; and the bright solar line which corresponds with 2796 (K) and with H γ is persistently called and identified with G, to the great scandal of the ghost of Fraunhofer and (I doubt not) the living Plücker. The blunder has often been repeated since, indeed I have seen it in NATURE more than once in the last few days. If it was not to have a Greek letter, at least it had a better right to be known as "2796 (K)" than has the coronal line to be called "1474 (K)." Failing that, it has been paraphrased, the shortest form being "near G." Surely it is time this were put right.

And now we have "1474." No one knows what the true position of that line is. The line 1474 (K) is an iron line, and it is to the last degree improbable that the coronal line is identical with it. The misnomer has carried with it, naturally, the idea that the source is iron. As this is an improbability of a higher order still—because there is evidence against it in the absence of a few hundred other iron lines—a false idea is in process of being fixed.

And all this arises, and much more will follow, from the laziness of mind, if I may so call it without offence, which adopts a name belonging to something already, instead of first reserving judgment, and giving it an independent standing with a name of its own.

Then there is the confusion of idea, and uncertainty in understanding exactly what is intended in speaking of the extension of the spectrum, and of position in it, as right and left, or left and right, as the case may be; or the confusion is avoided by the precise but cumbersome reference to degree of refrangibility. This is quite unnecessary. This is so exact an analogy between the degree of refrangibility and the degree of heat that no one

ought to experience the least difficulty in using the simple adjectives "higher" or "upper" and "lower" for the parts of the spectrum, and the simple prepositions "above" and "below," where required. There is no possibility of misconception, and no explanation is needed.

Probably we have got beyond the stage in which misconception is likely to arise from the careless use of words expressing continuity or otherwise in a spectrum; but I would suggest the word "diffuse" where it is not intended to express anything precise. Thus the coronal spectrum is diffuse until we know it to be solar. M. Janssen testifies to dark lines seen in the (diffuse) spectrum.

Turner's Vision

I HAVE been waiting since the appearance of a report of Dr. Liebreich's lecture in NATURE of March 21 expecting that an animated discussion would be provoked, affording me an opportunity of slipping in obscurely as a minor combatant, the subject being one on which I am but very indifferently qualified to speak, although thirteen years ago I did incidentally suggest an explanation of the peculiarities of Turner's later pictures which, simple as it is, still appears to me sufficient. On page 67 of "Through Norway with a Knapsack," published in 1859, speaking of some of the peculiar midnight sunset effects of the North, I said that "Turner, like an eagle, has dared to face the sun in his full glare, and to place him in the middle of his pictures, showing us how we see a landscape with sun-dazzled eyes, when everything is melted into a luminous chaos, and all the details blotted out with misty brightness."

In all these peculiar pictures that I have seen the sun is thus placed in the middle of the picture, and just sufficiently above the horizon (from about 10° to 20°, or at most 25°) to pour his rays about perpendicularly to the curvature of the eye-ball, when the face is in position to contemplate a landscape. I have frequently repeated the experiment of contemplating a landscape under such circumstances, and on every occasion of submitting to such torture have seen all the effects of even the most extravagant of Turner's later pictures, which are so well described by Dr. Liebreich. I have seen the "vertical streakiness, which is caused by every illuminated point having been changed into a vertical line," with an "elongation, generally speaking, in exact proportion to the brightness of the light," and that "there proceeds from the sun, in the centre of the picture, a vertical yellow streak." These appearances may arise from an affection of the crystalline lens of my eye similar to that attributed by Dr. Liebreich to Turner, or it may be due to something else much simpler, and which is more or less common to all human eyes. If the simpler explanation based upon normal conditions covers the facts, it certainly must be the more acceptable.

My explanation of the vertical streaks is this. When we thus look full faced at the sun, the dazzle produces slight inflammation or irritation, and a flow of tears. The liquid accumulates, and rests upon the lower eyelid, forming a little pool, the surface of which has a considerable vertical curvature, i.e. the lower part of the retained tear curves upwards from the surface of its base at the root of the lower eyelashes to its summit contact with the conjunctiva. Thus in a vertical direction it must act as a lens of very short focus, it must refract and converge the rays of light in a vertical plane, and thus produce a vertical magnifying effect, the definition of which will of course be very confused and obscure, on account of the irregular curvature, and the fact that the eye is focused to the distant objects. This want of directive focusing will limit the distortion to the bright objects whose vertically magnified images will be forced upon the attention.

To test this explanation let any one select a bright afternoon, and at about 6 P.M. or a little later, at this season, gaze sunward upon any landscape free from London smoke or other medium of solar obscuration. At first, if his eyes are not very sensitive, he will see a circular sun, but presently, as the tears accumulate, the vertical elongation of the sun and general "vertical streakiness" will appear. When I tried the experiment last week the sun appeared like a comet with a brilliant vertical conical tail, the point of which rested on the horizon. But I was then slightly troubled with what is called "a cold in the head," and my eyes watered very vigorously, and thus the conditions for producing fine Turnerian effects were highly favourable. On carefully drying my eyes these effects were, for a moment, considerably diminished.

I have adopted another method of testing this explanation. Having caused the eyes to become somewhat suffused, I bring the upper and lower eyelids so near together that the liquid shall occupy a sensible depth, i.e. from the conjunctiva to the base of both upper and lower eyelashes, and by compression be bulged or curved outwards in the vertical direction. On looking through this tear-filled chink at a gaslight, the vertical elongation is remarkably displayed, and it extends upwards or downwards or both according to the position of the liquid. When looking at the sun and landscape with the eyes fully opened (which is very painful), the elongation is chiefly downwards, and obviously connected with the tear on the lower eyelid; but if the eyelids be nearly closed to diminish the intensity of the light, an upward elongation is also commonly visible.

The other phenomena represented by Turner are, I think, simply a faithful copying of the effects of glare and suffusion produced by painful sun-gazing and the looking at a landscape where the shadows are, so to speak, nowhere, or all behind one's back.

W. MATTIEU WILLIAMS

The Adamites

As "M. A. I." prefers to keep his incognito, I shall not seek further to induce him to reveal himself. He has now, however, pointed out what he conceives to be errors in my paper, and I will reply to his criticism.

In the first place, as to the word *pi-ta*, I neither said nor inferred that the final syllable is not a suffix. My remark was that it retained a primitive root, *ta*, which is found also in the Semitic *'ata*, and I submit still that I am perfectly correct. The suffix *tir* in Sanskrit denotes nouns of agency, as Bopp shows in his "Comparative Grammar," and I am quite justified, when I find in various other languages a root word similar both in sound and sense, in inferring that the Sanskrit suffix was originally of the same character. I have hitherto been under the impression that comparative philology had established that suffixes were at one time independent words, but it appears that I am wrong. To show, however, that I have erred in good company, I would refer to Prof. Max Müller's "Stratification of Language" (p. 32), where it is said, "suffixes and affixes were all independent words, nominal, verbal, or pronominal; there is, in fact, nothing in language that is now empty, or dead, or formal, that was not originally full, and alive, and material." I must plead guilty of ignorance of "M. A. I.'s" scientific method.

As to *Taata*, when it is shown that *Tamata* or *Tangata* was the original form of the Polynesian deity's name, I shall be better able to reply to your correspondent's criticism. In any case, the final syllable is evidently the word denoting "spirit," and I see no difficulty in *Ta* becoming either *Tam* or *Tang* as the result of phonetic change. The mere fact that *Taata* and *Tiki* are different gods with different attributes really amounts to nothing, since such a division of personality and characteristics is a common fate of the divinities of heathen mythologies. I see no reason to change my opinion that the name of the Polynesian great ancestor has preserved the same primitive root as that which is to be found in the name of the first man, Adam, of the Semites, or rather of the *Akkad* forerunners.

While replying to "M. A. I.," it may be well to notice the criticism of his advocate, Mr. Jenkins, for whose explanation of the meaning of the word *Adam* I am much obliged, although, if he will take the trouble to read my paper, he will see that I was not ignorant of what he states. But the acceptance of the Hebrew meaning of the word as the original one does not lead me to place much reliance on Mr. Jenkins's judgment. If the Old Testament narrative proves anything beyond a knowledge of the tradition as to Adam, it is that the narrator was a bad philologist, and that finding the Hebrew word *adamah*, he forthwith inferred that the first man was made of ground-dust, which gave to him its red colour. For my part, I entirely ignore the authority on such a point of the Hebrew writer, and in justification I beg to refer to the statement made by the Rev. A. H. Sayce before the Society of Biblical Archaeology, as reported in the last number of NATURE (p. 495), that the early Semitic traditions are derived from an Akkadian source, as are also most of the biliteral roots of the Semitic language. If the traditions are taken from that source, the probability is that the proper names they enshrine have had the same origin; and I submit, therefore, that I am quite justified in tracing the meaning of the word Adam to the old Chaldean tongue, in which, as Mr. Norris's Assyrian dictionary shows, and as my paper asserts, *Ad* signifies "a father."

In conclusion, I may add that there is nothing improbable to my mind in peoples even so distant from each other as the Polynesian Islanders and the Gauls retaining in their traditions a name which had been applied to their mythical common ancestor, nor unreasonable in supposing that they and other peoples mentioned in my paper were alike derived from some region in Central Asia. My argument is simply cumulative, as there are many facts of a different kind pointing in the same direction.

I am sorry my communication has reached such an inordinate length; but having replied to "M. A. I.'s" objections, which, after his first letter, forcibly remind me of the mountain in labour bringing forth a mouse, I shall not trouble you with further correspondence on a subject which I fear is far from interesting to a majority of your readers.

C. STANILAND WAKE

Meteor

As I was going along the road towards Greystoke Castle at half-past eight P.M. on Friday last, April 19, I noticed a very fine meteor in a south-east direction. It was about the size of a common hand-ball, its centre being of an exceedingly brilliant white colour, surrounded by a circle of a bluish tinge, while short flickering radiations were distinctly visible on its circumference in all directions, reminding me of the spherio-stellate spicules of certain sponges. It was falling in a perpendicular direction, but I was not fortunate enough to see it at the beginning of its course. Its downward motion was slow and quite gradual, apparently not swifter than an ordinary india-rubber ball would fall by the gravity of its own body. There was no trail whatever left behind in its course. After two or three seconds it suddenly disappeared, before reaching the ground, without any explosion or expansion of its body. The night was very close and still, a muddiness covering the whole sky, interspersed here and there with long stratus clouds, and a beautiful halo surrounding the moon.

THOMAS FAWCETT

Blencowe School, Cumberland, April 22

A Waterspout

On Saturday last, April 16, whilst fishing in the river Elwy, at a point about two miles above the well-known Cefa caves, and five from St. Asaph by the river, I witnessed a very singular phenomenon. My attention was suddenly called up-stream by a remarkably strange hissing, bubbling sound, such as might be produced by plunging a mass of heated metal into water. On turning I beheld what I may call a diminutive waterspout in the centre of the stream, some forty paces from where I was standing. Its base, as well as I could observe, was a little more than two feet in diameter. The water curled up from the river in an unbroken cylindrical form to a height of about fifteen inches, rotating rapidly, then diverged as from a number of jets, being thrown off with considerable force to an additional elevation of six or seven feet, the spray falling all round as from an elaborately arranged fountain, covering a large area. It remained apparently in the same position for about forty seconds, then moved slowly in the direction of the right bank of the river, and was again drawn towards the centre, where it remained stationary as before for a few seconds. Again it moved in the former direction, gradually diminishing and losing force as it neared the bank, and finally collapsed in the shallow water. Strange to say, its course was perpendicular to the bank and not with the current.

At the time of the occurrence the river was still high, from the recent heavy rain, though the depth of water at the spot where I first observed it was not more than four feet. The current, of course, was stronger than usual, but presented a comparatively smooth surface. The day was fine and sunny, with a slight breeze from the S.E. The event occurred about 12.15, and lasted seventy or eighty seconds, as well as I could judge. The atmosphere in the immediate vicinity seemed, from the way in which the spray was scattered, to be somewhat agitated; but my impression was that such agitation was the result of the phenomenon, rather than its cause. I had fished over the spot a few minutes previously, and examined it afterwards with great care, but saw nothing to account for the wonder.

St. Beuno's College, St. Asaph, April 9.

J. GRAY

Cuckoo's Eggs

THE discussion raised by Prof. Newton on the coloration of cuckoo's eggs has been very interesting doubtless to many readers

of NATURE; a mite of information from New Zealand, concerning one species of the Cuculidæ, may not be out of place.

The German theory that "the egg of the cuckoo is approximately coloured and marked like those of the birds in whose nest it is deposited, that it may be less easily recognised by the foster parents as a substituted one," does not hold good in respect to our *Chrysococcyx lucidus*, Gml., pipiwharaupa, the whistler or small cuckoo.

The dupe is the pipiripi, or gray warbler, *Gygis flaviventris*, Gray, its eggs are white, dotted with red spots; the egg of the whistler of much larger size, is of a greenish dun.

However, I think it should be stated that the nest of the dupe is somewhat of a pear-shaped structure, firmly and thickly built, with a small entrance near the middle, well sheltered with feathers. Here discrimination betwixt eggs may be difficult for the foster parent, if it possesses the faculty and uses it. In the Trans. N.Z. Institute (vol. ii. pp. 58 and 65) reasons have been advanced by the writer for the selection of the warbler's nest by our brightly plumed cuckoo; may "thedin obscure" of its interior supply another reason?

THOMAS H. POTTS

Ohinitahi, Feb. 5

Sun-spots and the Vine Crop

As the connection of sun-spots with terrestrial phenomena is now largely occupying the attention of scientific men, the following facts may be of some interest. The years in which the vine crop in Germany was unusually good seem (in this century, at least) to have returned at regular intervals. The close coincidence of these years with the years of minimum sun-spots is shown by the following table:—

Minimum of Sun-spots.		Wine-years.		Minimum of Sun-spots.		Wine-years.
1784.8	...	1784		1833.8	...	1834
1798.5	...	(?)		1844.0	...	1846
1810.5	...	1811		1856.2	...	{ 1857
1823.2	...	1822				{ 1858
				1867.2	...	1868

I may add that the gentleman who first remarked the regular recurrence of wine-years at intervals of about eleven years was not aware of the periodicity of the sun-spots, and could not therefore have been in any way prejudiced. The years given in the above table are the only ones known in Germany as good wine-years.

These facts agree with the results of Messrs. Piazz Smyth and Stone, who found that the mean temperature on the surface of the earth was subjected to a period of eleven years.

ARTHUR SCHUSTER

Owens College, Manchester, April 23

Tide Gauge

IN NATURE of the 18th is a letter from Mr. Pearson respecting Tide Gauges. As very little appears to be known of such instruments, we beg to inform you that we have made them for many years, and have now two finished, one for the Indian Government, and the other for the Australian Government, and we shall be happy to show them to any one wishing to see them. We think they could be made self-acting at a much less cost if the exact time of high water is not required.

449, Strand, W.C., April 19

ELLIOTT BROTHERS

Colour of the Hydrogen Flame

IN a communication from my zealous science-master, which I find in your issue of Thursday the 11th, it is stated that pure hydrogen has no tinge of blue in its flame (that colour being due to the presence of sulphur), and he concludes his note with a gushing tribute of his own, and the younger boys' gratitude for the "simply delightful Science Primers of Profs. Huxley, Roscoe, and Balfour Stewart." Let me call his attention to the fact that on page 26 of his Chemistry Primer, Prof. Roscoe distinctly states that "Hydrogen is inflammable, and burns with a pale blue flame."

A GRATEFUL PUPIL OF MR. BARRETT

The "Cheironectes pictus"

SINCE I communicated to you an account of a fish which I caught in the Gulf weed during the homeward voyage of H.M.S. *Charybdis*, I have seen, in the February number of the *American*

Journal of Science and Arts, a description of a fish-nest which Prof. Agassiz obtained from the seaweed of the Sargasso Sea in December last.

In this interesting paper Prof. Agassiz identifies the embryos which he acquired from the nest as the young of the *Cheironectes pictus*, which, as its name implies, has fins like hands. From the description given I have no doubt but that my specimen is the *Cheironectes*, and I lose no time in forwarding to you the result of my reading.

J. E. MERYON

H.M.S. *Duke of Wellington*, Portsmouth

OCEAN CURRENTS

IN the *Philosophical Magazine* for October 1870 and 1871 I have examined at considerable length the arguments which have been advanced in favour of the theory that Oceanic Circulation is due to differences of specific gravity between the ocean in equatorial and polar regions. Since then a point in reference to the influence of the earth's rotation has suggested itself to my mind which appears to be wholly irreconcilable with the gravitation theory of currents.

It is one of the properties of a fluid that the resistance which it offers to motion is equal in all directions. It follows, therefore, that when an ocean current is flowing in any particular direction, the forces acting on the moving water must be greatest in the direction of motion. According to the theory that oceanic circulation is due to difference of specific gravity, resulting from the difference of temperature between the equatorial and polar waters, the direction of motion at the surface of the ocean is from the equator to the poles, and at the bottom from the poles to the equator, subject to a deflection caused by the earth's rotation. According to this theory gravity tends to impel the water from the equator towards the poles along the line of meridian; while rotation tends to deflect the water towards the east. If the total amount of work performed on the moving water by these two forces were equal, then the water on the northern hemisphere would take a north-easterly direction, and that on the southern hemisphere a south-easterly direction. But owing to the way in which the two forces vary in relation to each other, the path taken is not a straight line but a curve, the particular character of which has been determined with great labour by Mr. Ferrel.

But whatever view we may adopt in regard to the influence of rotation on the moving waters, whether it be that advocated by Dr. Colding and others, or that propounded by Mr. Ferrel, it is evident that if we assume the amount of the impelling energy of gravity to be not greater than the deflecting energy of rotation, we shall be led to the conclusions that there can be no such general interchange of equatorial and polar water in the Atlantic as Dr. Carpenter maintains. For under such conditions water leaving the equatorial regions for the Arctic seas would move as rapidly eastward as northward, and would consequently be deflected against the western coast of the old continent, and arrested in its progress before it reached even the latitude of England.

I need not, however, dwell further on this point, for I do not suppose there are any advocates of the gravitation theory who will not freely admit that the impelling energy is at least equal to the deflecting energy, and if this be admitted, it is all that is necessary for my present argument.

What proportion then does the impelling energy of gravity bear to the deflecting energy of rotation?

The velocity of rotation at the equator is about 1,526 feet per second, and at lat. 60° about 773 feet per second. Were water frictionless, and did it offer no resistance to motion, then a pound of water flowing from the equator in the direction of the pole would, on arriving at latitude 60° , have, according to hitherto received ideas, an easterly velocity relative to the earth's surface of 763 feet per second. Mr. Ferrel has, however,

shown that the relative velocity would be much greater. But not to run the risk of over-estimating the velocity, I shall be content to take it at 763 feet. Water flowing from the equator towards the poles, instead of having an actual velocity of 763 feet per second on reaching latitude 60° , has, at the utmost, a velocity not over one or two feet. If we suppose the velocity to be, say, 3 feet per second, then 766 feet per second of velocity derived from rotation is consumed by friction and other resistances in the passage of the water from the equator to that place. A pound of water moving with a velocity of 766 feet per second possesses in virtue of that velocity 9,025 foot-pounds of energy. This enormous amount of energy is all consumed, not in impelling the pound of water from the equator to latitude 60° , but in simply deflecting it to the east during its motion. Consequently 9,025 foot-pounds is the amount of energy required to perform the work of deflection. But since the resistance offered by a fluid to motion is equal in all directions, the resistance offered to the impelling force must be as great as that offered to the deflecting force. It is, I trust, admitted that in the passage of the pound of water from the equator to latitude 60° , the distance traversed by the water under the influence of the impelling force is as great as the distance traversed under the influence of the deflecting force, or, in other words, the distance from the equator to latitude 60° , measured along the meridian, is as great as the distance to which the water is deflected to the east during its passage. Then, if this be the case, 9,025 foot-pounds of energy of the impelling force must be also consumed in overcoming the resistance to the motion of the pound of water; that is, the impelling force requires to perform 9,025 foot-pounds of work before it can convey a pound of water from the equator to latitude 60° . Can gravitation, therefore, be the impelling force? Can gravity, according to Dr. Carpenter's theory, perform 9,025 foot-pounds of work on a pound of water in impelling it from the Equator to latitude 60° ?

Taking Dr. Carpenter's own data as to the temperature of the ocean at the poles and equator, and the rate at which the temperature at the equator decreases from the surface downwards, I have shown* that 9 foot-pounds is the greatest amount of work which gravity can perform on a pound of water (placed under the most favourable circumstances) in carrying it from the equator to either pole. Assuming the slope from the equator to the poles to be uniform, 6 foot-pounds will be the total amount of work that gravity can perform upon a pound of water in its passage from the equator to lat. 60° . But this is only $\frac{1}{1506}$ part of the amount of energy required. Hence, if there is any circulation of water between the equatorial and polar regions, it must be produced by a cause 1,506 times more powerful than the one to which he appeals.

But in reality the amount of energy impelling the water must be far more than 1,506 times greater than what can be derived from gravity, for the water moves more in the direction of the impelling force than in the direction of the deflecting force, thus proving that the impelling force is greater than the deflecting force.

Although it will be admitted that the resistance offered by fluid friction is equal in all directions, yet it may be urged that, owing to the influence of the winds or some other cause or causes which I have not taken into account, the actual resistance to motion may be greater in some directions than others. This no doubt may be the case, but it cannot possibly affect the conclusion at which I have arrived, unless it be shown that the resistance to pole-ward motion is 1,506 times less than the resistance to eastward motion.

But these results are as conclusive against the theories of Maury, Colding, Ferrel, and in fact against every possible form of the gravitation theory, as against the theory of Dr. Carpenter. And I need hardly add that they are equally fatal to the theory that ocean currents are caused

* Phil. Mag., Oct. 1871.

by the heaping up of the water by the winds; for any amount of power which could possibly be derived from such a source must fall enormously short of that required.

It may be noticed that we have here a means of making a somewhat rough estimate of the absolute amount of resistance offered to oceanic circulation, a rather obscure point. It shows that the resistance to motions arising from friction is far greater than was hitherto supposed. The amount of the work of the resistance to a pound of water passing from the equator to lat. 60° would not be less than twice 9,025 foot-pounds.

It follows also that if the resistance to motion in the waters of the ocean be as great as it has thus been proved to be, then there is no warrant for the generally received opinion that a force such as that of the winds acting on the surface of the ocean cannot produce motion extending to any considerable depth. For if the resistance to motion be as great as the foregoing consideration shows it to be, it is impossible that the upper layers of the ocean can be constantly pushed forward in one direction without dragging the underlying layers after them.

The inadequacies of the gravitation theory may be shown in an even still more striking manner. Conceive a column of water in any part of the ocean extending from the surface to the bottom. Suppose the column to be a foot square, and the depths of the ocean to be four miles. We have in this case a column a foot in thickness, and four miles in height measured from its base. According to Dr. Carpenter's theory, gravity tends to move the water forming the upper part of the column in the direction from the equator to the pole, and the water forming the under part from the pole to the equator. What then is the amount of force exerted by gravity on the entire column? In the next part of my paper on Ocean Currents in the *Philosophical Magazine* I shall demonstrate by an exceedingly simple and obvious method, that the total amount of force exerted by gravity on the whole mass of water constituting the column is only $\frac{1}{16}$ of a grain. That is, $\frac{1}{16}$ of a grain on 600 tons of water.

Edinburgh, April 15

JAMES CROLL

THE FOSSIL MAMMALS OF AUSTRALIA

THE substance of this communication was given orally at the meeting of the Royal Society, April 18, 1872.

Prof. Owen commenced by alluding to the series of fossils brought in 1836 by the then Surveyor-General of Australia, Sir Thomas Mitchell, from the bone caves discovered by him in Wellington Valley, New South Wales. The determination of these remains required study of the osteology and dentition of the existing marsupial animals, which formed the subject of papers in the "Transactions of the Zoological Society" (vol. ii., 1838, and vol. iii., 1845).

In these papers indications were given of a second species of living wombat, distinct from the type peculiar to Tasmania, such indications being yielded by a skull sent from Australia. In 1853 the author published, in his "Osteological Catalogue of the Museum of the College of Surgeons," the cranial characters of a third living species of *Phascolomys*, also from a skull, which, like that of the second species, was from the continent of Australia. These materials seemed to some naturalists inadequate for the acceptance of a *Phascolomys latifrons* and a *Phascolomys platyrhinus*, in addition to the first discovered Tasmanian *Phascolomys vombatius*; and Gould in the part published in 1855 of his great work, "The Mammals of Australia," containing the fine figure of that species, hesitated to admit more, although a drawing which he had received of the head of a wombat killed in South Australia "afforded good reason for concluding that the continental animal is really distinct." In 1859 this distinguished

naturalist was able to publish in Part XI. of his work a figure of a wombat from the southern parts of the continent of Australia, which he recognised as distinct from the small wombat of Tasmania, and referred to the *Phascolomys latifrons*; it was, however, the larger bare-nosed species, *Phascolomys platyrhinus*.

In 1865 and 1866 specimens were received at the Zoological Gardens of London, of both the continental Australian wombats, which the able Prosecutor, Dr. Murie, showed to have respectively the cranial characters of *Phascolomys latifrons* and *Phascolomys platyrhinus*. The *Ph. latifrons* had the nose or muzzle clothed with hair. This confirmation greatly encouraged the speaker in the investigation and comparison of the cranial and dental characters of the fossil remains of the genus; and in November 1871, he felt that he had grounds for submitting to the Royal Society such characters of four other species of wombat, not exceeding in size the largest of the existing kinds, which four species appeared to have become extinct on the continent of Australia. The differentiation of the actual platyrhine and latifront species from some of the extinct forms was not the less interesting and instructive; though it seemed small in degree, it was, however, definite, in comparison with other fossil remains which could not be distinguished from the existing *Phascolomys platyrhinus* and *Ph. latifrons*.

The determination of the species propounded on cranial and dental characters in the present paper was much easier and more decisive, by reason of the marked superiority of size of the fossils. These large and gigantic wombats were differentiated, not only by bulk, but by modifications of the skull and proportions of certain teeth, notably the incisors and premolars.

On these grounds the author characterises a *Phascolomys medius*, which, although markedly larger than *Phascolomys platyrhinus*, was intermediate in bulk between the two now known extremes of size in the genus. Next followed a *Phascolomys magnus*, and finally a *Phascolomys gigas*. Of the latter species a restoration was given in a diagram of the natural size, which was that of a tapir or small ox. The dental and certain cranial characters were illustrated by highly finished drawings of the fossils.

With respect to the large extinct wombats described in his present paper, the author remarked that it was not likely they could have escaped detection if still existing in any of the explored parts of the Australian Continent. The knowledge that such species have existed may excite to research and help to their discovery, if any of them should still be in life, in the vast tracts of the northern and warmer latitudes of Australia.

The author exhibited in a tabular view the localities of the known existing and extinct Australian wombats as follows:—

Where found	By whom found	Species of <i>Phascolomys</i>
Breccia Cave, Wellington Valley, N. S. Wales	Sir Thomas Mitchell, C.B., 1836	<i>Mitchelli</i>
Lacustrine Bed, Victoria	E. C. Hobson, M.D., 1845	<i>Gigas</i>
Drift Deposits, Queensland	Geo. Bennett, M.D., F.L.S., 1861	<i>Mitchelli</i>
16. King's Creek, Darling Downs	S. Turner, 1847	<i>Parvus, Medius</i>
16. Gowrie, 16.	Fred. Neville Isaac, 1861	<i>Mitchelli</i>
16. Eton Vale, 16.	Ed. S. Hill, 1865	<i>Platyrhinus, Medius, Magnus, Gigas</i>
16. St. Jean Station, 16.	M. Satche St. Jean, 1864	<i>Gigas</i>
16. Drayton, Queensland	Sir Daniel Cooper, Bt., 1865	<i>Thomsoni, Medius</i>
Freshwater Beds, Clifton Plains, 16.	F. Nicholson, 1866	<i>Gigas</i>
Caves, Wellington Valley, N.S. Wales	Professor Thomson, G. Krefft, 1867	<i>Mitchelli, Krefftii, Latifrons</i>

The author then touched upon some generalisations suggested by the present stage of discovery. The disappearance of the larger species was explicable on the principle of the "contest of existence," as applied by him to the problem of the extinction of the fossil birds of

* "On the Fossil Mammals of Australia," No. VIII.: Genus *Phascolomys*; species exceeding the present in size, by Prof. Owen, F.R.S.

New Zealand (Trans. Zool. Soc., vol. iv., 1850), and subsequently by Darwin to the incoming of new species, as "the battle of life." He next entered upon the relation of the present discoveries in Australia to the law of Geographical Distribution in the new Tertiary or Quaternary periods of extinct and existing animals.

The wombat was a more characteristic Australian form of mammal than the kangaroo, for the latter is represented by species in New Guinea; and species of *Phalanger* range farther from Australia, though still bound to the same great natural, and mainly submerged, division of the earth's surface. But no kind of wombat, recent or fossil, has been detected out of Australia and Tasmania. The present Continental kinds, and species near akin to them, existed in Australia during a very long period, reckoned by the terms of historical time, if we may judge from the state of petrification of the fossils, and the great depths at which some have been met with in well-digging; where, after 30 ft. or 40 ft. of black rich soil have been bored through, such fossils occur at 100 ft. lower down in sandy drift, which has been accumulated to that or greater vertical thickness beneath the loam. On the assumption that air-breathing animals perished in a general deluge some 5,000 years ago, and that their disappearance then began anew from the exceptional few individuals preserved in the Ark, we must suppose the wombats then living in Australia to have contributed miraculously their pair or pairs to the Asiatic menagerie, and to have been as miraculously restored to their proper continent on the subsidence of the Noachian flood.

It is neither creditable nor excusable that so great a divergence should still be maintained, chiefly through theological teaching, in the ideas of the majority of men "of ordinary culture" as to the cause and conditions of the distribution of living species over the globe, from those suggested by the clear and multiplied demonstrations of Science. On this topic the author referred to a paper in "Annals and Magazine of Natural History," 1850, "On the Gigantic Birds of New Zealand, and on the Geographical Distribution of Animals."

THE CONNECTION BETWEEN COLLIERY EXPLOSIONS AND WEATHER*

AFTER a preliminary reference to previous papers on the subject, and especially to the diagrams published by Mr. Joseph Dickinson, and by Mr. Bunning, of Newcastle-on-Tyne, the authors of the paper referred specially to Mr. Dobson's paper, published in the reports of the British Association. They showed that the periodicity alleged by him to exist in these explosions had no real foundation in fact; for, on plotting the dates of the explosions for the last twenty years in two ten-year periods, very slight resemblance was seen between the two curves. The number of accidents (all fatal ones) on which the statement was based was 1,369.

In the progress of this inquiry it had come out that the number of serious accidents, involving the loss of ten lives or more, had materially increased during the last five years, the numbers being:—

1851-55 . . . 13.	1856-60 . . . 15.
1861-65 . . . 12.	1866-70 . . . 21.

These numbers appear to be well worthy of remark.

For the special purpose of the paper, the continuous records from Stonyhurst, one of the observatories in connection with the Meteorological Office, were taken, and the curves for the barometer and thermometer were plotted for the three years, 1868-70. The records of fatal explosions were obtained from the published reports of the inspectors, while the dates of the non-fatal accidents were obtained from the inspectors themselves, who, almost

without exception, replied to the communications addressed to them, and furnished the desired information.

Mr. Dobson, in his paper, having spoken of the explosions occurring principally at the commencement of a storm, the authors showed that it was not, in some cases, until two or three days after the barometer had reached its lowest point that the accident happened. They showed also why, during a period of continued violent oscillation of the barometer, the passage of each successive barometrical minimum is not characterised by an equal number of explosions, the largest groups of accidents being reported when a serious break occurred after a period of calm weather.

The effect of a high temperature of the air in interfering with ventilation, and especially with natural ventilation, was also explained, and it was shown how the first hot days in spring were marked by explosions.

The actual dates of the explosions for the three years in question were then compared with the meteorological records, and it was shown that out of 550 explosions—

266,	or 48 per cent.,	might be attributed to the state of
		the barometer;
123,	" 22 "	to the state of the thermometer;
161,	" 30 "	remained unaccounted for on meteorological grounds.

The next point touched upon in the paper was the action of a more or less impure ventilating current in increasing the explosive character of the air in all parts of the pit, and possibly in causing an explosion in a place which would have remained safe had the ventilating current itself remained pure. It was shown how, when an explosive mixture had been formed in places and under conditions similar to those described, some time, possibly several days, must elapse before the contents of such an accumulation of dangerous gases shall have been rendered innocuous again.

The effect of warm weather in stopping natural ventilation was explained. The natural temperature of a mine of the depth of 50 fathoms being 55°, that of one of the depth of 200 fathoms 70°, and so on (speaking generally), it was shown that if the temperature of the air rose to 55° natural ventilation must cease in shallow pits, and similarly in other cases. Accordingly, if a warm day occurs in the cold season of the year, and the furnaces are not in action, an explosion is very likely to occur.

These statements were illustrated by one instance of a fatal explosion, the cause of which had been declared by the inspector to be inexplicable, the pit having "strong natural ventilation." It appeared, however, that the explosion occurred on a warm day, while the inspector visited it twice on colder days after the explosion; so that the state of ventilation which he witnessed had no reference to that which must have prevailed when the accident happened.

The paper concluded by stating that it appeared that the evidence fairly justified the view that meteorological changes are the proximate causes of most of the accidents, it being remembered, as has before been observed, that the records contain no account of the number of times when the pits have been too dangerous for the men to go down, and so explosions have not happened.

Whatever be the meteorological changes, it is absolutely necessary to keep a most careful watch over the amount of air passing through the workings.

Thirty years ago George Stephenson said, in a letter to the South Shields Committee, referring to explosions:—"Generally speaking, there has been some fault in the ventilation of the mines when accidents have occurred;" and the same opinion is held by many of the most experienced authorities at the present day. In this matter the one cry, whether we look to security against explosion, or to the affording to miners an atmosphere which they can breathe without injury to health, is "More air!"

* "On the Connection between Colliery Explosions and Weather," by Robert H. Scott, F.R.S., and Mr. W. Galloway. Read at the meeting of the Royal Society, April 18, 1872.

THE TEMPERATURE OF THE SURFACE OF THE SUN

It will be recollected that Messrs. M. E. Vicaire and Sainte-Claire Deville read some papers before the Academy of Sciences at Paris last January, showing that the temperature of the solar surface does not exceed that produced by the combustion of organic substances. Their reasoning being based on the law of radiant heat established by the investigations of Dulong and Petit. I have in the meantime instituted a series of experiments on a comparatively large scale, in order to test the correctness of the said law. Accordingly, the dynamic energy developed by the radiation of a mass of fused iron weighing 7,000 pounds raised by "overheating" in the furnace to a temperature of $3,000^{\circ}\text{F}$., has been carefully measured.

Sir Isaac Newton assumed that the quantity of heat lost or gained by a body in a given time is proportional to the difference between its temperature and that of the surrounding medium. Some eminent scientists, however, accepting Dulong's conclusions and formula, assert positively that the stated assumption is incorrect. In so doing they apparently overlook the conditions inseparable from the Newtonian doctrine, namely, that the conducting power of the radiating body should be perfect; that at every instant the temperature pervading the interior mass should be transmitted to the surface.* It needs no demonstration to prove that if the conducting power of a body be so perfect that the temperature of the centre is at all times the same as that of the surface; in other words, that the fall of temperature at the centre, occasioned by radiation, is as rapid as the fall of temperature at the surface, the rate of cooling of such a body will be very different from that observed by Dulong and Petit. The investigation instituted by those experimentalists has in reality established only the degree of conductivity of the radiators employed, under certain conditions, but by no means their true radiant energy at given temperatures. M. E. Vicaire and Sainte-Claire Deville, therefore, commit a serious mistake in assuming that the *quantity* of heat transmitted by the radiation of incandescent bodies at high temperatures has been determined. It may be observed that the relation between the time of cooling and the *quantity* of heat transmitted by radiation which Dulong and Petit established, also misled Pouillet regarding the temperature of the solar surface, which he computed at $1,461^{\circ}\text{C}$., or at most $1,761^{\circ}\text{C}$. It will be well to bear in mind that Pouillet had himself ascertained with considerable accuracy the temperature produced by solar radiation on the surface of the earth; and also the retardation suffered during the passage of the rays through the terrestrial atmosphere. He was therefore able to demonstrate that the dynamic energy developed by solar heat amounts to nearly 300,000 thermal units per minute for each square foot of the surface of the sun. Considering the imperfect means employed by Pouillet, his "pyrheliometre," the exactness of his determination of solar energy is remarkable. The truth is, however, that the near approach to exactness was somewhat fortuitous, the eminent physicist having underrated the energy of radiant heat on the surface of the earth, while proportionately over-estimating the retarding influence of the terrestrial atmosphere. The true dynamic energy developed by

radiation at the surface of the sun, exclusive of the absorption of the solar atmosphere—no doubt exceedingly small—determined by the solar calorimeter mentioned in a previous article, is 312,500 thermal units per minute upon an area of one square foot. It will be proper to notice that this amount is not a mean result of a number of observations, but the greatest energy developed at any time during observations continued upwards of three years, namely February 28, 1871. It will be proper to add that this result has been withheld from publication until it could be verified by a second observation indicating an equal energy. Fortunately the sky at noon, March 7, 1872, proved to be as clear as on the previous occasion referred to, the indicated energy differing only a few hundred units from that developed February 28, 1871.

Temperature being a true index of molecular and mechanical energy, conclusively established by the exact relation between the degree of heat and the expansive force of permanent gases under constant volume, it is surprising that Pouillet did not perceive that an intensity of $1,461^{\circ}\text{C}$. or $1,761^{\circ}\text{C}$., could not possibly develop on a single square foot of surface the enormous energy represented by 300,000 thermal units per minute. M. Vicaire, adopting like Pouillet Dulong's formula, states in the paper presented to the French Academy that "an increase of 600° is sufficient to increase the radiation a hundred fold;" and that Pouillet has verified Dulong's law to more than $1,000^{\circ}$. "Supposing," he observes, "that beyond this temperature the law ceases to be true, it cannot be absolutely remote from the truth for the temperatures of from $1,400^{\circ}$ to $1,500^{\circ}$ which we deduce by adopting the law." Sainte-Claire Deville concludes his essay on solar temperature thus:—"In accordance with my first estimate I believe that this temperature will not be found far removed from $2,500^{\circ}$ to $2,800^{\circ}$, the numbers which result from the experiments of M. Bunsen, and those published long ago by M. Debray and myself." The French *savants* then agree that the temperature of the surface of the sun does not exceed the intensity produced by the combustion of organic substances, their grounds for this assumption being, as we have seen, Dulong's formula relating to the velocity of cooling at high temperatures. But Dulong and Petit did not carry their investigations practically beyond the temperature of boiling mercury; hence their formula relating to high temperatures is mere theory, the soundness of which we have now been enabled to test most effectually by measuring the radiant power of a mass of fused metal raised to a temperature of $3,000^{\circ}\text{F}$., 30 inches in depth, presenting an area of 900 square inches.

Before describing the means which have been employed in measuring its radiant power, let us briefly consider the condition of the fused mass during the experiments. In the first place, the temperature has been sufficiently high to produce an intense white light, luminous rays of great brilliancy being emitted by the radiant surface during the trial; (2) the bulk of the fused mass being adequate, the intensity of radiation has been sustained without appreciable diminution during the time required for observation; (3) the temperature being higher than that which the French investigations assign to the surface of the sun, while the bulk, as stated, is sufficient to maintain the temperature of the fused mass, it may be reasonably asked, why an area of one square foot of our experimental radiator should not emit as much heat in a given time as an equal area on the solar surface, if its temperature be that assumed by Pouillet? It may be positively asserted, moreover, that an increase of the dimensions of our radiator to any extent, laterally or vertically, could not augment the intensity or the dynamic energy developed by a given area. Again, Dulong's formula, as applied by scientists, shows that the emissive power of a *metallic* radiator raised to a temperature of $3,000^{\circ}$, reaches the enormous solar intensity computed by Pouillet.

Let us now briefly examine the calorimeter constructed

* The writer has just completed a set of experiments with a spherical radiator, 2.75 in. in diameter, composed of very thin hammered copper, charged with water kept in motion by a wheel applied within the sphere, revolving at a rate of 30 turns per minute, the centrifugal action of which brings the particles of the central portion of the fluid so rapidly in contact with the thin spherical shell, that the apparently absurd condition of perfect conductivity has been practically fulfilled. The result of carefully conducted experiments with this radiator, enclosed in an exhausted vessel kept at a constant temperature, has established that Newton's law relating to radiant heat, up to a differential temperature of 100°Fahr . (beyond which the investigation has not extended), is rigorously correct. The subject will be fully discussed in a future article.

for ascertaining the mechanical energy developed by the radiation of the fused mass under consideration. Fig. 1 represents a vertical section, and Fig. 2 a perspective view. *a* is a cylindrical boiler, having a flat bottom, composed of thin sheet-iron 0.012 inch thick, coated with lamp-black. The cylindrical part of this boiler is surrounded by a concentric casing *b*, the intervening space being filled with a fire-proof non-conducting substance. A horizontal wheel, *c c*, provided with six radial paddles, is applied within the boiler, attached to a vertical axle, *d*. An open cylindrical trunk, *g*, is secured to the perforated disc which supports the paddles. The vertical axle passes through the top of the boiler, a conical pinion being secured to its upper termination. By means of a vertical cog-wheel, *h*, attached to the horizontal axle *k*, and geared into the conical pinion, rotary motion is communicated to the paddles. The centrifugal action of the latter will obviously cause a rapid and uniform circulation of the water contained in the boiler—indispensable to prevent the intense radiant

heat from burning the bottom. The boiler and mechanism thus described are secured to a raft, *l l*, composed of fire-bricks floating on the top of the fluid metal. By this means it has been found practicable to keep the bottom of the boiler at a given distance, very near the surface of the fused mass, while by moving the raft from point to point, during the observation, irregular heating resulting from the reduction of temperature of the surface of the metal, under the bottom of the calorimeter, has been prevented. The radiant heat being too intense to admit of the axle *k* being turned directly by hand, an intervening shaft, eight feet long, provided with a crank handle at the outer end, has been employed for keeping up the rotation of the paddle-wheel during the trial. It is scarcely necessary to observe that, the intervening shaft should be coupled to the gear work by means of a "universal joint," to admit of the necessary movement of the raft. The experiment, repeated several times, has been conducted in accordance with the following explanation. The boiler being charged,

Fig. 1

the paddle wheel should be turned at a moderate speed while observing the temperature of the water, the thermometer employed for this purpose being introduced through an opening, *m*, at the top of the boiler. The temperature being ascertained, the instrument should be quickly placed on the raft, and the time noted. As soon as vapour is observed to escape through the opening at *m*, the instrument must be instantly removed, the time again noted, and the temperature of the water within the boiler ascertained. It will be well to keep the paddle-wheel in motion until the last observation has been concluded.

The temperature of the fused metal having been as high during our experiments as that of the solar surface computed by Pouillet and his followers, while the thin substance composing the bottom of the calorimeter has been brought almost in contact with, and consequently received the entire energy transmitted by, the radiant surface, the reader will be anxious to learn what amount of dynamic energy has been communicated in a given

time, on a given area. The desired information is contained in the following brief statement:—The necessary corrections being made for heat absorbed by the materials composing the paddle-wheel, &c., the instituted test shows that the temperature of a quantity of water weighing 10 pounds avoirdupois has been elevated 121° F. in 164 seconds (2.73 minutes), the area exposed to the radiant heat being 63 square inches. Hence a dynamic energy

$$\frac{10 \times 121}{2.73} \times \frac{144}{63} = 1013 \text{ thermal units per minute, has}$$

been developed by the radiation from one square foot of the surface of the fused metal maintained at 3,000° F., against 312,500 units developed by the radiation of one square foot of the solar surface, the temperature of which, agreeably to the calculations of the French *savans*, is less than that of our experimental radiator.

Having thus ascertained practically the amount of dynamic energy developed by the radiation of a metallic body raised to the high temperature of 3,000°, we have only to show in a similar manner the amount of energy

developed by a metallic radiator of a low temperature, to be enabled to demonstrate the correctness or fallacy of Dulong's formula. Numerous experiments have been made for this purpose with apparatus of different forms, the results having proved substantially alike. The device most readily described consists of a spherical vessel charged with water, suspended within an exhausted spherical enclosure kept at a constant temperature. Repeated trials show that, when the differential temperature is 65° , the enclosure being maintained at 60° , while the sphere is 125° , the dynamic energy transmitted to the enclosure by a sphere the convex area of which is one square foot, amounts to 5.22 thermal units per minute. The accuracy of this determination is confirmed by the fact that during the summer solstice at noon, when the sun's differential radiant intensity is 65° , the solar calorimeter indicates a dynamic energy of 5.12 units per minute on one square foot of surface.

Our practical investigations, then, show that a differential temperature of $3,000^{\circ}$ develops by radiation a dynamic energy of $1,013$ thermal units per minute upon an area of

one square foot; and that a differential temperature of 65° develops 5.22 units per minute upon an equal area. The ratio of radiant energy at the first mentioned inten-

sity will therefore amount to $\frac{1013}{3000} = 0.337$ units for each degree of differential temperature; while for the low intensity it will be $\frac{5.22}{65} = 0.080$ unit for each degree of differential temperature.

Consequently, the ratio of the radiating energy will be $\frac{0.337}{0.080} = 4.21$ times greater at $3,000^{\circ}$ than at 65° . Now, M. Vicaire, on the authority of Dulong, states that the ratio will be a hundred fold greater for an increase of only 600° . According to Newton's theory, based on dynamic laws, the proportion between the differential temperature and the radiant energy of bodies is constant; while Dulong and Petit, basing their conclusions upon an erroneous estimate of the time of cooling, assert that the ratio of energy increases

Fig. 2

several thousand times when the temperature is increased from 65° to $3,000^{\circ}$. Newton, then, as our experiments prove, is incomparably nearer the truth than the French experimenters; and possibly future research will prove that his law, when properly applied, will be found absolutely correct. It should be mentioned that the result of our experiments with the fused metal, compared with the result of other experiments with solid metals at various temperatures, show that the emissive power of cast iron is relatively greater in a state of fusion than when solid, or merely incandescent. This observed increase of emissive power, now being thoroughly investigated, will no doubt account for the deviation from the Newtonian law indicated by the preceding comparison, which, let us recollect, is based upon the difference of radiant energy of fused metal at $3,000^{\circ}$, and solid metal at 65° . Considering this extreme range of temperature, and the totally different conditions of the radiators, the observed discrepancy is not too great to admit of satisfactory explanation. The fallacy of Dulong's formula relating to high tem-

peratures having been conclusively shown, it will not be necessary to examine the calculations of Messrs. M. E. Vicaire and Sainte-Claire Deville, presented to the Academy of Sciences at Paris. Besides, the question of solar temperature cannot be properly investigated without considering the leading points connected with the propagation of radiant heat through space—a subject of too wide a range to be discussed in this article. It should, however, be mentioned that the result of the measurement of solar intensity March 7, 1872, before referred to, proves the correctness of our previous demonstrations, showing that the temperature of the surface of the sun is at least $4,036,000^{\circ}$ F.

J. ERICSSON

THE CYCLONE IN THE WEST INDIES

A CORRESPONDENT in your number of October 12, 1871, expresses a wish for an article to appear in your paper, on the Cyclone which passed over Antigua, and several other of the Leeward Islands in the West

Indies, on the 21st of August last. If no other better qualified person has complied with that wish, I beg leave to tender the following account.

Perhaps a few preliminary observations in reference to the working of the barometer in these parts of the Tropics are necessary. A well-regulated mercurial barometer, at or about the sea level, under all ordinary conditions of the atmosphere, with the trades blowing from the east, stands at 30.00 or 30.10. A south-east wind, and the approach of heavy rains, will cause the barometer to fall, at times, to 29.80. At other times a N.E. trade wind, if not a storm wind—though it may bring occasional heavy showers—will cause the barometer to rise to 30.30. Thus the range of the mercury in these islands, when no cyclone is passing, is limited to five-tenths of an inch; but the variation seldom exceeds three-tenths. The atmospheric tide (if I may so call it), which causes the barometer to rise and fall half-a-tenth twice in the twenty-four hours, is very distinctly marked in these islands. The barometer being the highest at 10 A.M. and 10 P.M., and the lowest at 4 A.M. and 4 P.M. Any variation from this rule during the hurricane season calls for vigilance.

The following observations of the movements of the barometer during the late cyclone were taken at an elevation of about twenty-five feet above the sea-level.

The hurricane season of this year was preceded by a long dry season, and though the months of June and July were very hot, and sometimes oppressive, we had very little thunder and lightning. During the month of July we had some very squally weather, but the barometer was not much influenced by it. During the latter part of July and the first weeks of August, the wind often shifted towards the north, which is quite unusual at that time of the year, the barometer at the same time falling below 30.00. These indications caused some anxiety in the minds of those who were accustomed to observe the state of the weather.

The first indications of the approaching storm were noticed at 10 o'clock on the morning of the 20th. A light, but instead, wind was blowing at the time from E.N.E., the barometer had not risen after 4 A.M. as usual, and though standing at 30.00, the surface of the mercury was concave, indicating a fall. During the day the wind continued to blow moderately, but in gusts; the barometer slowly falling. Between 4 and 5 o'clock P.M. there was a heavy squall of wind and rain from N. by E., followed by a comparative calm. The appearance of the sky at sunset was most remarkable and alarming to those who understood anything of the indications of an approaching storm. A pale, sickly light, of a coppery hue, was spread over every object, and continued some time after sunset; and at the same time there was the appearance of a wind-gale in the east. At this time I sent a notice of the approaching storm to those living on the North-east coast, a part of the island likely to be very much exposed to its fury. Some persons did the best they could to secure their houses; but because there was no heavy swell in the sea, the fishermen disregarded the warning, and consequently lost their boats.

It is a singular fact, that about 6 P.M. the barometer not only ceased to fall, but a slight rise was perceptible, which at first led to the supposition that the storm might be only passing, and not approaching, the island. This hope was soon dissipated by the increasing force of the gusts of wind, with another squall of wind and rain about 9 P.M. with a falling barometer.

At midnight the barometer had fallen to 29.50, or about half an inch. Between two and three o'clock A.M., the wind shifted more towards the east, blowing with increased violence, breaking off the branches from the trees, and stripping shingles from the houses; but up to this time no great damage had been done. About 3.30 A.M., a singular circumstance occurred—one which I have never witnessed before, though, during a residence of thirty-three

years in these islands, I have experienced many cyclones. The barometer ceased to fall for half an hour; the mercury standing firm at 29.30. This, for the time, led to the conclusion, which soon proved to be erroneous, that the centre of the storm was then passing, and that we had experienced the worst of it. At 4 A.M., the barometer again began to fall, at first slowly, and afterwards rapidly, until, at 6.40, it stood at 28.57, having fallen about an inch and a half below its usual height.

As the barometer fell, the gusts of wind became more violent, shaking large and strongly-built houses to their very foundations, tearing off verandahs, spouting, and window-shutters, and, in some instances, carrying them to great distances. Between 5 and 6 A.M. we experienced the full force of this fearful storm, and it was about this time that a large number of houses, both in town and country, with churches, school-rooms, and estate works, were destroyed.

It was soon after 5 A.M. that the writer was able, from a sheltered position, to have a full view of the awful grandeur of the storm. Low, black clouds, like dark ocean billows driven rapidly overhead; the driving rain like sheets of water; the trees whirled round and beaten nearly to the earth, until rooted up or broken off; the constant flashing of intensely red lightning, with the heavy crash of thunder, mingling with the roaring of the wind—altogether, formed a scene grand and terrific in the extreme; but which was well worth the risk to witness.

About 7 A.M. the centre of the storm passed the south of the island; the barometer began to rise, and the wind changed to S.E. and S. The storm had entirely passed over by 10.30 A.M.

The centre of this storm just touched the extreme south of Antigua; passed directly over St. Kitts, where a calm of twenty minutes was experienced, before the wind burst from the opposite quarter; and also over St. Thomas and Tortola. From thence it passed over the southern islands of the Bahama group. After that I have not been able to trace its course.

Antigua was the first island over which the hurricane passed. Being a comparatively level island—all the high land being situated at the extreme south—it suffered the most severely. Nevis and St. Kitts having mountains from 2,000 to 3,000 feet high, which broke the fury of the storm, only suffered severely in certain parts, principally on the north and east coasts. As the destruction caused by this hurricane has been fully detailed by the newspapers, I need not dwell on that subject in the present paper, but will proceed to state some interesting particulars in reference to the movements of this cyclone.

Its course appears to have been nearly from E. by S. to W. by N. As there was no heavy sea on the shores of Antigua, within a few hours of its arrival, it is evident that it originated within 200 or 300 miles of the island, and during the first hours of its existence was by no means a violent storm.

Its progressive movement was also very slow at first. The first circles struck Antigua soon after 4 P.M. on Sunday, but the centre did not pass until 7 A.M. on Monday; whilst the last half of the storm was only three hours in passing over. It is also evident that from 3.30 to 4 A.M., during the time that the barometer ceased to fall, its progressive movement was altogether suspended, though the rotary motion continued.

After 4 A.M. it began to move with great rapidity, and travelled at a speed, which, as far as I know, has not been equalled by any previous hurricane among these islands. The centre of this cyclone passed Antigua at 7 A.M., and arrived at St. Kitts at 9 A.M., having travelled at the speed of thirty miles per hour. In that island the lofty range of mountains not only broke the force of the rotary motion, but also impeded its progress; so that between St. Kitts and St. Thomas, a distance of 160 miles, it travelled at a

speed of a little more than twenty-two miles per hour, the centre arriving at St. Thomas about 4 P.M. on the 21st. What was the speed and force of its rotary motion, I have no means of correctly ascertaining; but there is no doubt that near the centre it very greatly exceeded that of its progressive motion. The diameter of the storm was about eighty miles, the outer circles taking in at the same time Montserrat in the south, and Barbuda in the north; but was not felt beyond those islands. In its progress towards the west and north it may have extended itself, as is frequently the case with these storms.

On the afternoon of September 25, we again had indications of an approaching cyclone, though not so marked and distinct as on the former occasion. The gale set in about 10 P.M., from N. by E., and continued till 10 A.M. on the 26th, the wind changing to N.N.W. and S.W. The centre just touched the north of the island at 4 A.M. on the 26th. The force of the wind was at no time very great, and did not prove destructive on land—though causing much anxiety and alarm during its progress. The barometer did not fall on this occasion more than half-an-inch.

G. W. WESTERBY

Antigua

PROFESSOR S. F. B. MORSE

INTELLIGENCE has already been received in this country of the death of Samuel Finley Breese Morse, the eminent electrician, who died at New York on the 2nd inst. at the age of eighty-one. Prof. Morse was the son of the Rev. Jedediah Morse, well known as a geographer, and was born at Charlestown, Massachusetts, on the 27th of April, 1791. He was educated at Yale College, but, having determined to become a painter, he came to England in 1811, formed a friendship with Leslie, and in 1813 exhibited at the Royal Academy a colossal picture of "The Dying Hercules." He returned to America, and for a few years followed the profession of a portrait painter. In 1829 he again visited England, and on his return voyage was accompanied by Prof. Jackson, the eminent American chemist and geologist, through whose influence he turned his attention to the conduction of electricity through metallic wire, a subject in which the chemical tastes displayed by him while at College gave him additional interest, and to which he now devoted the whole powers of his mind.

Between 1835 and 1837 Prof. Morse invented several machines which more or less foreshadowed the electric telegraph; and obtained from Congress a vote of 30,000 dollars, with which to make an experimental essay between Washington and Baltimore. The first electric telegraph completed in the United States was the line between these cities, which was finished in 1844. Since that time the Recording Electric Telegraph of Morse has been adopted over the whole country, and at the time of his death there were not less than twenty thousand miles of electric wires, stretching over the States between the Atlantic and the Pacific Ocean.

Prof. Morse received during his life recognition of his services to science from a large number of foreign Governments and scientific societies, not the least remarkable being the one inspired by the late Emperor of the French. At his suggestion delegates from France, Russia, Sweden, Belgium, Holland, Austria, Sardinia, Tuscany, the Holy See, and Turkey, met at Paris, and voted an award of 400,000 frs. to Prof. Morse as a testimonial of appreciation of his services.

A record of Prof. Morse's scientific career would not, however, be complete, without referring to a controversy which some years ago occupied the attention of the scientific world in the United States, in which he was engaged with Prof. Henry, now President of the Smithsonian Institution at Washington. So much personal matter was introduced

into the dispute that a special committee of the Board of Regents of the Smithsonian Institution was appointed to investigate the matter, the report of which now lies before us. The result of this investigation is summed up as follows:—

"We have shown that Mr. Morse himself has acknowledged the value of the discoveries of Prof. Henry to his electric telegraph; that his associate and scientific assistant, Dr. Gale, has distinctly affirmed that these discoveries were applied to his telegraph, and that previous to such application it was impossible for Mr. Morse to operate his instrument at a distance; that Prof. Henry's experiments were witnessed by Prof. Hall and others in 1832, and that these experiments showed the possibility of transmitting to a distance a force capable of producing mechanical effects adequate to making telegraphic signals; that Mr. Henry's deposition of 1849 . . . is strictly correct in all the historical details, and that, so far as it relates to Mr. Henry's own claim as a discoverer, is within what he might have claimed with entire justice; that he gave the deposition reluctantly, and in no spirit of hostility to Mr. Morse; that on that and other occasions he fully admitted the merit of Mr. Morse as an inventor; and that Mr. Morse's patent was extended through the influence of the favourable opinion expressed by Prof. Henry."

The conclusion therefore which must be arrived at, and it is one of no small importance in the history of electrical and telegraphic science, is that to Prof. Henry, and not to Prof. Morse, is unquestionably due the honour of the discovery of a principle which proves the practicability of exciting magnetism through a long coil, or at a distance, either to deflect a needle or to magnetise soft iron.

Prof. Morse's services to science as a successful applier of this principle in its practical details are so unquestionable, that we feel we are but doing a duty in setting this question right on this side the Atlantic.

NOTES

THE following are the names of the candidates who have been selected by the Council of the Royal Society for admission into that body at the forthcoming annual election:—Surgeon-Major Andrew Leith Adams, Prof. W. G. Adams, F. Le Gros Clarke, M.R.C.S., Prof. John Cleland, M.D., Dr. M. Foster, Dr. Wilson Fox, Dr. Arthur Gamgee, Rev. Thomas Hincks, Prof. W. Stanley Jevons, Prof. T. Rupert Jones, Dr. George Johnson, Major T. G. Montgomerie, R.E., Dr. E. L. Ormerod, E. J. Routh, and Dr. W. J. Russell.

AT the meeting of the Royal Geographical Society, held on Monday evening last, a letter was read addressed to the President by Dr. Kirk, H.B.M. consul at Zanzibar, in which that gentleman expressed himself very hopefully of Dr. Livingstone's safety. He thinks there is nothing discouraging in the last news received of him, and that we cannot expect to hear again until the war at Unyanyembe is closed.

H.R.H. THE DUKE OF EDINBURGH will hold a reception on Saturday evening next in the Picture Galleries of the International Exhibition and in the Royal Albert Hall, on behalf of the Prince of Wales and the Royal Commissioners.

WE understand that Lieut-Colonel Strange, F.R.S., will exhibit at the ordinary meeting of the Royal Society on Thursday, May 2nd, the Great Theodolite designed by him for the Great Indian Trigonometrical Survey of India, and will read a paper descriptive of it.

THE electors of the Waynflete Professorship in Chemistry at Oxford have given notice that it is their intention to proceed to the election of a Professor some time in Act term next. The endowment assigned to the Professorship is 600*l.* per annum,

payable out of the revenues of Magdalen College. The residence required by the College ordinance is six calendar months, at least, between the 10th day of October in every year and the first day of the next ensuing July. By the same ordinance the College may require certain services from the Professor; but the functions and duties of the office are mainly regulated by a statute of the University, the provisions of which, as well as of the College ordinance, may be obtained from the President of Magdalen, to whom persons intending to become candidates are requested to send in their names, and any papers which they may wish to present to the electors in support of their application, on or before the 18th of May.

THE next triennial prize of 300*l.* under the will of the late Sir Astley T. Cooper, Bart. will be awarded to the author of the best essay or treatise on "Injuries and Diseases of the Spinal Cord." The essays or treatises shall contain original experiments and observations, which shall not have been previously published, and each essay or treatise shall be illustrated by preparations, and by drawings, which shall be added to the Museum of Guy's Hospital, and shall, together with the work itself, become henceforth the property of the Institution. Essays must be sent in to Guy's Hospital on or before January 1, 1874. If written in a foreign language they must be accompanied by an English translation.

RADCLIFFE Studentships for persons studying medicine, and desirous of making use of the museum and lectures at Oxford, have been awarded to Mr. Francis T. Carey, of Guy's Hospital, and Mr. C. R. B. Keetley, of St. Bartholomew's Hospital, on the recommendation of Sir James Paget, Sir William Gull, and Dr. John Ogle; and to Mr. Farington M. Granger, of the Hospital of Leeds, on the recommendation of T. P. Teal, M.A., M.B.

M. STEWART of Rossall School has been elected to the Exhibition of 50*l.*, at St. John's College, Cambridge, tenable for three years, for Natural Science. The examiners also honourably mentioned Anderson, of Rugby School, and King's College, London. There were seven candidates. The examiners were—Chemistry, Mr. Main; Physics, Mr. A. Freeman; Physiology, Dr. Bradbury; Geology, Mr. Bonney; Botany, Mr. Hiern.

CAPTAIN G. S. NARES will, on his arrival in England from the Mediterranean, commission the unarmoured screw corvette *Challenger* for special exploring and surveying duties in the Pacific. The *Challenger* is a vessel of 2,306 (1472) tons and 1509 (400) horse power.

It is proposed, according to the *American Naturalist*, to add a department of Science to the executive branch of the United States Government. It is to be composed of the Storm Signal Corps of the army, the Lighthouse Board, and the Coast Survey Bureau of the Treasury, and the Hydrographic Bureau of the Navy.

WE hear that a proposition is on foot to establish an Agricultural-Meteorological station at Montrouge, near Paris, under the superintendence of M. Ch. Moureaux.

A COMMUNICATION to the Corporation of Brown University, in America, was recently presented from Colonel Stephen T. Olney, making a munificent offer of his herbarium and books on botany, on condition that a suitable building should be provided for their reception. It was referred to a committee.

THE officers of the Boston (U.S.) Young Men's Christian Union, recognising the importance of scientific studies and the need of encouraging scientific tastes, have determined to establish in the rooms of the Union a natural history cabinet. Their object in providing such a collection is to foster the growing taste for science among the young men of Boston, and to open a new source of instruction and amusement to the members of the Union.

A VERY interesting collection of water-colour drawings made by Mr. W. Simpson, on the various excavations below the modern city of Jerusalem, which have been carried on for the past three years by the Palestine exploration, under the superintendence of Captain Warren, of the Engineers, is now placed for exhibition in the Gallery, 48, Pall Mall. Most of the drawings are taken in the excavations or in the sacred tombs and caves; but the artist has made his series complete by two or three which represent the massive walls of Jerusalem as they are now to be seen above ground, as well as that part of them which has been discovered at the depth of 125 ft.

AT the meeting of the Manchester Literary and Philosophical Society on March 19, the President, Mr. E. W. Binney, read an elaborate paper, entitled "Additional Notes on the Lancashire Drift Deposits."

AT the Annual Meeting of the Bengal Social Science Association, Dr. Ewart, the president, delivered an excellent address on the necessity for the introduction into the schools preparing students for the entrance examination of the University of Calcutta, of the study of the rudimentary principles of the natural and physical sciences. Although the University was avowedly founded on the model of the London University, the traditional policy of the older Universities is apparent in the exclusion of Science; and a movement commenced last year to introduce examination in various branches of science has at present failed. Dr. Ewart points out with great force the injury which the higher education has suffered in England from a similar course, and that the "existing metaphysical system of education is fast flooding the country with a class of gentlemen who cannot find occupation suitable to the kind and nature of the training they have received." "Are we to wait here," he inquires, "simply to follow in the wake of England in this matter? Is India to go through a long embryo state of preparation like the Western nations, extending over many centuries?"

A NEW technical paper has been started at Brussels, entitled *Chronique de l'Industrie*, answering to our English papers, the *Engineer* and *Engineering*.

DR. J. L. PFEIFFER, of Cassel, has published the two first parts of a work which will be indispensable to every systematic botanist, "Nomenclator Botanicus," being an alphabetical enumeration of the names of all classes, orders, tribes, families, divisions, genera, sub-genera, and sections of plants, published down to the end of the year 1858, with copious references to the authorities, systematic arrangement, synonymy, and first publication. From the care evidenced in the parts already published, the work will supply a desideratum long felt in botanical literature; and the author, who is an amateur man of science holding no official position, deserves the thanks of all botanists. Arrangements are made by which the work may be carried down to the present time.

MR. C. P. HOBKIRK, of Huddersfield, announces as in course of preparation, A Synopsis of the British Mosses, in 1 vol. 8vo.

THE long-expected translation of Le Maôut and Decaisne's "Traité Général de Botanique," by Mrs. J. D. Hooker, is announced by Messrs. Longman as in the press.

MESSRS. BRADBURY AND EVANS have in the press "Botany for Beginners," by Dr. Maxwell T. Masters, F.R.S., a portion of which has already appeared in the columns of the *Gardener's Chronicle*.

A VERY interesting series of articles on the animals contained in the Crystal Palace Aquarium, by Mr. Edward Newman, F.L.S., is now being published in *The Field*.

THE Catalogue of Microscopical Preparations in the Quckett Microscopical Club, consisting of about 2,000 slides, is chiefly

of interest from the plan on which they are classified. The arranging and cataloguing a large collection of microscopical preparations in a satisfactory manner is admitted to be a work of considerable difficulty. In the present instance the catalogue is divided into five groups, containing Vertebrata, Invertebrata, Phanerogamia, Cryptogamia, and Mineral Substances. Each of the groups Vertebrata and Invertebrata is again subdivided into orders; and the Phanerogamia into stems, fibres, cell structure, cuticles, hairs, pollen, seeds, and starches. The Cryptogamia are subdivided into ferns, mosses, fungi, characeae, algae, desmids, and diatoms. The minerals are without subdivision. Although this classification is open to some objections, yet, on the whole, it was perhaps about the best which could have been done with the materials; and the catalogue, which is on sale for the benefit of microscopists generally, will furnish a long list of objects for those who are collecting. In some of the subsections—as, for instance, the hairs of bats, fructification of ferns, and microscopic seeds—the cabinet appears to be remarkably complete. Indeed, it is doubtful whether these sections can be equalled in the cabinet of any other society.

In a letter to the Minister of Foreign Affairs, brought before the French Academy on February 26, a report is given of the earthquake shock felt at Malaga on January 28 at 3^h 1^m P.M. The undulatory movement lasted from four to six seconds, and subterranean noises were heard previously to the shock. The direction was from north to south. No damage is reported.

The *American Journal of Science* gives an account of the earthquake of the 9th of January experienced in New England. It occurred over a considerable portion of Eastern New England and the St. Lawrence Valley, at a few moments before 8 P.M. on January 9. It was felt along the St. Lawrence River to a distance of 200 miles north-east and 60 miles south-west from Quebec, and at various points of New Hampshire and Maine. The disturbance was greatest at Quebec, where some walls were cracked, and large fissures caused in the ice bridge over the river. The shock occurred there at 7:54 P.M. and lasted about thirty seconds, being accompanied by a low rumbling sound. At Lancaster, in New Hampshire, there were two distinct shocks, each lasting but a few seconds, the last being the most violent. The direction of vibrations was well defined, and approximately west to east. Probably the true direction was from a point somewhat south of west, which would coincide nearly with the course of the St. Lawrence River, and with the shorter diameter of the region shaken. At Quebec and Bangor slight shocks were felt at 3 P.M. and 11 P.M. on the same day.

The towns of Dresden, Perna, Schandau, Chemnitz, Bodenbach, Wurmar, and Rudolstadt, were visited almost simultaneously by a succession of earthquake shocks between three and four o'clock on Wednesday, March 6. They continued to recur during an hour, and in some instances during several hours. Little damage was done.

A CORRESPONDENT of the *Times*, telegraphing from Alexandria, states that half the town of Antioch was destroyed by an earthquake on April 3. Fifteen hundred persons were killed. Great distress prevails in consequence. The shock was also felt at Aleppo, but without any damage being done.

We have received the second part of the Proceedings of the Bristol Naturalists' Society for 1871. Like other similar publications which we have had occasion to notice recently, it contains no original articles bearing on the natural history of the district, or containing original observations. The proceedings of the Sections are also rather scant, though they bear evidence of some work having been done in Geology and Entomology.

WE have received a series of chemical labels published by Messrs. Mottershead and Co., of Manchester. The labels are printed in good legible type, better than is usual in such cases, the backs being gummed ready for use. No definite system of chemical nomenclature has been used, in many instances the common or old names of the reagents are given, although perhaps in some cases to the sacrifice of scientific accuracy. Contrary to the usual practice, no symbols are attached, the publishers preferring to leave space for the insertion of these, according to the views held by each chemist. At the end of the reagents a number of slips are attached, with the words "pure," "commercial," &c., to qualify the foregoing labels. The total number given is considerable, forming a very good and cheap series (*gd.*)

OBSERVATIONS OF THE AURORA BOREALIS OF FEBRUARY 4 & 5, 1872 *

THE splendid aurora by which our sky was illuminated yesterday evening was remarkable for the great variety of appearances which it displayed, for its intensity, its duration, and lastly for the large expanse of sky over which it spread. In fact it exhibited collectively all the principal phenomena observed in former appearances of this meteor: that is to say, luminous arches of various colours, dark arches, moveable clouds of red and green colour, bright rays both isolated and united in large bundles, dark rays, diverging and converging rays, red pillars, changes of colour, &c., &c. It lasted from about six o'clock till after midnight, whereas in most cases the duration of the phenomenon does not exceed a few hours, and is not unfrequently less than an hour. The auroral light, under various forms and colours, extended over nearly the whole of the sky, whereas it is usually limited to the northern region.

The want of magnetic instruments prevented me from foreseeing by their perturbations the approach of the phenomenon, so that I did not perceive it till about 6h. 30m. by which time it was already developed in vast proportions. I arrived, however, in time to observe all the principal phases, and to analyse the various coloured lights with the spectroscope.

Although the numerous phenomena observed in this aurora did not present anything actually new, still their detailed description will be of great advantage to science, as exhibiting the order of their succession and their mutual relations and dependences. Such scope, however, could be attained only by a long and systematic description; and for the present I must limit myself to an account of my spectroscopic observations.

The greenish yellow light which illuminated certain arches and isolated clouds, and likewise the part of the sky near the magnetic meridian, appeared, when examined by the spectroscope, to be monochromatic, its spectrum being almost wholly concentrated in a beautiful green line, the position of which was very near the division 1241 of Kirchhoff's scale.

In the brightest parts nearest to the magnetic meridian, and in a few yellow rays near the zenith, I discovered, by means of the spectroscope, a second green line situated towards the blue, and corresponding very nearly with the division 1820 of Kirchhoff's scale. The line 1241 is near a known line of iron, and 1820 is near a known line of atmospheric air.

The second green line was very much less bright than the first, but nevertheless very distinct. Between these two lines were traces of several other faint lines, the position of which I was unable to determine.

On the decidedly red mass I could not make out any distinct bright line, but only certain bands of continuous spectrum. On the yellow-red mass I detected the bright line 1241, without any distinct lines in the red.

The spectroscopic observations were continued with the same results till about the middle of the night, when the aurora had almost entirely vanished.

The atmospheric conditions during the phenomenon were normal, only a few masses of cloud being seen from time to time near the horizon; and I observed an appearance which seemed to me especially worthy of notice—namely, a continuous glow proceeding from the horizon towards the S.E., by which some clouds and a stratum of mist were lighted up almost continuously

* Translated from the *Gazzetta Ufficiale del Regno d'Italia*, Feb. 6.

and with considerable brightness, chiefly from half-past eight to ten o'clock.

During the phenomenon several falling stars were observed, and a magnificent bolide in the Great Bear at 8h. 30m., but this was probably accidental.

This evening, in the expectation that the aurora borealis might reappear, I began to observe the sky as soon as twilight was over, and I perceived a faint glow, a kind of phosphorescence, diffused over the whole sky, but without any decided appearance of boreal light.

While waiting for more imposing phenomena, I directed the spectroscope towards the zodiacal light, to ascertain whether its spectrum could be observed at Rome, as it had been observed on the Red Sea on the evening of the 11th, and the morning of the 12th January last.

Angström, in 1867, found the spectrum of the zodiacal light to be monochromatic, consisting of a single green line, to which he assigned approximately the position 1259 on Kirchhoff's scale, the same that he had determined for the green line of the aurora borealis; and I myself, on the days above mentioned, was able to perceive in the zodiacal light, not only this green line, but near it and towards the blue, a band or zone of apparently continuous spectrum.

This evening at seven o'clock, I was able to discern the same spectrum in the light above mentioned; and on directing the spectroscope to other points, I found that this spectrum showed itself in all parts of the heavens from the horizon to the zenith, more or less defined in different parts, but everywhere as bright as in the zodiacal light. The observatory assistant, Dr. di Legge, likewise observed this spectrum distinctly, in various parts of the heavens.

This fact, which corroborates an analogous observation made by Angström in 1867, appears to me of the greatest importance, inasmuch as it demonstrates the identity of the zodiacal light with that of the aurora, and thereby tends to establish the identity of their origin, and to unite into one these two mysterious phenomena.

L. RESPIGHI

Observatory of the Royal University of Campidoglio,
Feb. 5, 1872.

PHYSIOLOGY

Note on Recurrent Vision*

IN the course of some experiments with a new double plate Holtz machine, belonging to the college, I have come upon a very curious phenomenon, which I do not remember ever to have seen noticed. The machine gives easily intense Leyden jar sparks from seven to nine inches in length, and of most dazzling brilliance. When, in a darkened room, the eye is screened from the direct light of the spark, the illumination produced is sufficient to render everything in the apartment perfectly visible; and what is remarkable, every conspicuous object is seen twice at least, with an interval of a trifle less than one quarter of a second—the first time vividly, the second time faintly; often it is seen a third, and sometimes, but only with great difficulty, even a fourth time. The appearance is precisely as if the object had been suddenly illuminated by a light at first bright, but rapidly fading to extinction, and as if, while the illumination lasted, the observer were winking as fast as possible.

I see it best by setting up in front of the machine, at a distance of eight or ten feet, a white screen having upon it a black cross, with arms about three feet long and one foot wide, made of strips of cambric. That the phenomenon is really subjective, and not due to a succession of sparks, is easily shown by swinging the screen from side to side. The black cross, at all the periods of visibility, occupies the same place, and is apparently stationary. The same is true of a stroboscopic disc in rapid revolution; it is seen several times by each spark, but each time in the same position. There is no apparent multiplication of a moving object of any sort.

The interval between the successive instants of visibility was measured roughly as follows:—A tuning fork, making 92½ vibrations per second, was adjusted, so as to record its motion upon the smoked surface of a revolving cylinder, and an electro-magnet was so arranged as to record any motion of its armature upon the trace of the fork: a key connected with this magnet was in the hands of the observer. An assistant turned the

machine slowly, so as to produce a spark once in two or three seconds, while the observer manipulated the key.

In my own case the mean of a dozen experiments gave 0° 22' as the interval between the first and second seeing of the cross upon the screen; separate results varying from 0° 17' to 0° 30'. Another observer found 0° 24' as a result of a similar series.

Whatever the true explanation may turn out to be, the phenomenon at least suggests the idea of a *reflection of the nervous impulse* at the nerve extremities—as if the intense impression upon the retina, after being the first time propagated to the brain, were there reflected, returned to the retina, and from the retina travelling again to the brain renewed the sensation. I have ventured to call the phenomenon "Recurrent vision."

It may be seen, with some difficulty, by the help of an induction coil and Leyden jar; or even by simply charging a Leyden jar with an old-fashioned electrical machine, and discharging it in a darkened room. The spark must be, at least, an inch in length.

Hanover, February 9

SCIENTIFIC SERIALS

Annales de Chimie et de Physique, July and August, 1871.

This number contains the second portion of a very lengthy memoir by M. Berthelot on explosive agents in general; this half of the communication deals with dynamite, gun cotton, picric acid and potassic picrate. At the end of the memoir a general table is given which shows the amount of heat generated and the volume of gas formed by one kilogram of substance; the product of these two numbers will of course give the relative effects produced by each compound; the numbers given show that if nitroglycerine produces an amount of force equal to 94, picric acid equals 54, gun cotton 50, potassic picrate 34, whilst gunpowder has only an explosive force equal to 14. M. Janssen contributes a very valuable paper on the atmospheric lines in the solar spectrum. He finds that the bands observed by Brewster and Gladstone can be resolved into fine lines comparable to the solar lines properly so called, and that the atmospheric lines are more numerous than the solar lines in the red, orange, and yellow portions of the spectrum. The atmospheric lines are always visible in the solar spectrum, some lines it is true almost disappear when the sun is very high, but they are those which are never very intense; the author finds that the intensity of the atmospheric lines observed at the horizon is about fifteen times as great as when observed in the meridian. M. Janssen has also examined the spectrum of the moon and stars, and more particularly of Sirius and α in Orion; he has not succeeded in observing any new lines whatever in the spectrum of the moon, proving that our satellite cannot have any appreciable atmosphere. M. Raoult has found that a solution of cane sugar sealed up in vacuo and exposed to light for five months is partially changed into glucose. Amongst the other original memoirs there is a very long one by Dr. de Coppet on the temperature of congelation in saline solutions. There are also a considerable number of abstracts of papers from foreign journals, making up altogether a very bulky number.

THE *Journal of the Quekett Microscopical Club*, No. 18, April 1872, contains the following three communications:—"Observations on the Polyzoa, by A. H. H. Lattey, M.R.C.P." This paper is chiefly devoted to the preparation of the Polyzoa for the microscope, so as to exhibit them in permanence with the tentacles expanded.—"On the so-called 'nerve' of the Tooth," by T. C. White, Hon. Sec. The principal elements met with in a microscopical examination of what is popularly termed the "nerve" of the tooth, are here indicated, and suggestions are given to assist in the more complete examination of tooth-structure.—"On the Internal Structure of the *Pulex irritans*," by W. H. Furlong. This is a second communication on the structure of the flea which has been submitted to the club by its author. The first was occupied chiefly in the examination of external organs, the present is devoted to internal structure, commencing with the alimentary and digestive system, then following remarks on the respiratory system, and finally observations on the reproductive system. The embryology is left untouched, to form the subject of a third and concluding paper, which will then embrace the life history of one of the commonest, but not the least interesting, of British insects. The club announced its list of excursions for the season com-

* From the *American Journal of Science and Art* for April. By Prof. C. A. Young, of Dartmouth College.

mening April 6, and terminating October 5. There are fifteen excursions, of which fourteen are announced for Saturday afternoons, one whole day excursion, and one day excursion ending with the excursionists' annual dinner. The annual *soirée* of the club was held at University College on Friday evening, March 22, and was attended by about 1,200 persons.

Journal of the Chemical Society, February. — Dr. Armstrong contributes a paper "On the nitration products of the dichlorophenolsulphonic acids," being a continuation of his researches published in recent numbers of this journal. The next communication is on Eulyte and Dyslyte, by H. Bassett, being a re-examination of these bodies, which were briefly described by Baup in 1851. The third and last original communication is by Dr. Howard, "On Quinine and Cinchonine and their salts." Some time since the author gave an account of an amorphous alkaloid from cinchona bark, the properties of which distinguished it from those already described. Further investigations, however, have shown that it is probably identical with quinine, first obtained by Pasteur by the action of heat on quinine. The author finds that the quinine obtained from quinine, and that obtained from quinidine, are identical in their properties. Several salts of cinchonine have been prepared; there is considerable resemblance between them and the quinine salts, although the former are somewhat more soluble. The same identity is observed between the cinchonines obtained from cinchonine and from cinchonidine as was observed in the case of quinine. The action of these alkaloids on polarised light confirms the identity already mentioned. Thus, the quinine prepared, either from quinine (which possesses a strong left-handed rotation), or from quinidine (which has a right-handed rotation), exhibit a feeble right-handed rotation, which, in each case, is almost identical. The abstracts of papers in foreign journals occupy seventy-pages, and, as usual, are of great interest.

Verhandlungen der k. k. geologischen Reichsanstalt zu Wien. Nos. 3 and 4. The articles in these numbers are for the most part of local interest; but we notice a short sketch of the geological structure of East Greenland by F. Toula—some of the fruits of the last German expedition—which will be read with interest. Literary and other notices, as usual, occupy considerable space in the proceedings.

THE *Geological Magazine* for April 1872 (No. 94) opens with an excellent article from the pen of Mr. W. Davies, of the British Museum, on the rostral prolongations of the singular Liassic Fish, described by Agassiz under the name of *Squaloraja polycephala*. The two projecting processes from the snout of this fish were regarded by Dr. Riley and Prof. Agassiz as forming a single rostrum; but Mr. Davies argues with justice that the upper one is really a cephalic spine analogous to that met with in a similar situation in the male Chimæridæ, and that it was employed, as by them, in conjunction with the elongated rostrum, for securely clamping the female. Mr. Davies refers to other points in the anatomy of this curious fish, which he illustrates with a large plate.—Prof. Dyer commences the description of some remains of coniferous plants from the lithographic stone of Solenhofen; the form here described is named by him *Aracurites Haberlinii*.—From Mr. Searles Wood, jun. we have a paper on the climate of the post-glacial period, and a reply to Mr. James Geikie's Correlation of the Scotch and English Glacial beds, whilst the last-mentioned author contributes a fifth paper on Changes of Climate during the Glacial epoch.—Some points in the Geology of the East Lothian coast, form the subject of a paper by Messrs. G. W. and F. M. Balfour, in which they describe the peculiar relations existing between the porphyry of Whiterby Point and the adjacent sedimentary (sandstone) rocks, the latter being found to dip on all sides towards the mass of porphyry. The authors suppose the porphyry to have been erupted through a small orifice, and to have caused the depression of the sedimentary beds by pressure.

The original articles in the March number of the *American Naturalist* are not so numerous as usual. Prof. J. D. Biscoe commences with a description of the breathing-pores or stomates of leaves.—Prof. H. W. Parker describes the meteorological phenomena witnessed in the western prairies, including the very common occurrence of parhelia in mock suns.—Dr. R. H. Ward has some remarks on uniformity of nomenclature in regard to microscopic objectives and oculars, of considerable interest to microscopists.—The most important article is "On

the Stone Age in New Jersey," by Dr. Chas. C. Abbott, illustrated with a number of woodcuts of the rude implements and utensils found throughout that State, the relics of its original Indian inhabitants.

SOCIETIES AND ACADEMIES

LONDON

Geological Society, April 10.—"Notice of some of the Secondary Effects of the Earthquake of the 10th January, 1869, in Cachar." Communicated by Dr. Oldham, of Calcutta, with remarks by Mr. Robert Mallet, C.E., F.R.S. This earthquake was a severe one, being strongly felt in Calcutta, distant from the meizoseismic area about 200 miles, and far into the plain of Bengal. The effects were examined on the spot a few weeks after the shock by Dr. Oldham, who anticipates being able to fix the position and depth of the centre of impulse by following the same methods as those first employed by Mr. Mallet with respect to the great Neapolitan earthquake of 1857. These results have not yet been received; but Dr. Oldham has forwarded an extremely interesting letter on the circumstances of production of very large earth-fissures, and of the welling up of water from these, derived from the water-bearing ooze-bed, upon which reposed the deep-clay beds in which the fissures were formed. Dr. Oldham rightly views all these fissures, which were all nearly parallel to and not far distant from the steep river banks, as "secondary effects," and not due to fractures produced by the direct passage of the wave of shock. He also shows that the welling up or overflowing of the water in the fissures was a secondary effect also, and negatives the notion entertained on the spot of mud-volcanoes, &c., having originated at those fissures. The chief aim of Mr. Mallet's remarks was to point out the importance to geologists of rightly comprehending the dynamics of production of these phenomena, and to show that the older notions of geologists as to earthquake-fissures are untenable. He explained clearly, aided by diagrams, the train of forces by which the elastic wave of shock, on passing out of the deep-clay beds where these have a *free side* forming the steep river banks, dislodges certain portions and throws them off towards that free side—and that this is but a case of the general law in accordance with which such elastic waves behave towards more or less incoherent deposits reposing on inclined or on level beds, under various conditions. Mr. Mallet also explained the dynamic conditions under which the water from water-bearing beds, such as that of ooze beneath the Cachar clay beds, becomes elevated in the fissures formed, and gave approximate expressions for the minimum height to which the water can rise in relation to the velocity of the elastic wave particle. The paper concluded with some explanatory remarks upon the continual noises, like the irregular fire of distant artillery, heard long after the shock had passed, and when the country had become perfectly quiescent. The noble collection of photographs which were made by Dr. Oldham, and forwarded to Mr. Mallet, illustrative of the physical features of the huge earth-fissures and other effects of this earthquake, were exhibited to the Fellows present, and are well worthy of attentive study. Sir Henry James inquired whether there was any trace of fissuring in the lower beds beneath the slimy ooze. Mr. Scott wished to ascertain the author's opinion as to the possibility of predicting earthquakes on meteorological grounds, as had been done by M. Boullard, several of whose prophecies were said to have been fulfilled. Mr. D. Forbes gave some details of the earthquake of Mendoza, a town situated on a vast alluvial plain at the foot of the Andes, in which the phenomena remarkably coincided with those detailed by Dr. Oldham. In that case he found that the rumours as to fire and smoke having been emitted from fissures were entirely without foundation, the presumed smoke having been nothing but dust. The earthquake was felt over a distance of 1,200 miles; and wherever the firm rock came to the surface there was no trace of fissure, though portions of the rock were overthrown. But in the plain, consisting of 30 or 40 feet of alluvial soil, the whole ground was in places fissured, and in some districts the surface completely furrowed, and even the turf turned over. He had witnessed numerous earthquakes, and in some cases had been in deep mines during their occurrence, when the sound only could be heard, and he could testify to their effects being confined to the surface. The direction of the fissures was invariably at right angles to the line of shock. In South America all the earth-

quakes could be traced to volcanic centres. The President inquired as to the distinction to be drawn between the primary and secondary effects of earthquakes, and whether the author thought that no fissures were attributable to the direct action of earthquakes. As to the cause of the sound, like that of a cart carrying iron bars or of an artillery wagon, he wished for further information. Mr. Mallet, in reply, explained that fissures only take place where masses were comparatively free in one direction. They might extend to enormous depths, though they often closed in rapidly. With regard to the power of predicting earthquakes, he disbelieved in it wholly, and considered that any fulfilment of such prophecies must be due to accident; earthquakes are so numerous, that the chances of such fulfilments are great. The blow or impulse originating earthquakes could not be attributed solely to one cause. It arose often from deep subterranean volcanic action; but it also—especially in the case of long-continued tremors, like those of Comrie or Pignerol—arose from the breaking up or the grinding over each other of rocky beds at a great depth, through the tangential pressures produced in the earth's crust by secular cooling. The arrested impulse of the fall of the Rosberg in Switzerland produced a sensible earthquake. Fissures in hard rock could not be produced directly by the shock, because the velocity of impulse in such rock greatly exceeded that of the elastic wave particle. The earth's crust was at present not in a state of tension, but of compression, through secular cooling.

Zoological Society, April 16.—Dr. E. Hamilton, vice-president, in the chair. A letter was read from Dr. R. Schomburgk, of the Botanic Gardens, Adelaide, South Australia, containing an account of the apparently reasonable conduct of a monkey kept in the gardens.—Mr. A. H. Garrod, Prosecutor to the Society, read a paper on the mechanism of the gizzard in birds, in which he endeavoured to show that the ordinary action of this organ was that of compression, and not of trituration as usually understood.—A communication was read from Dr. John Anderson, on a supposed new monkey from the Sunderbunds to the east of Calcutta, allied to *Macacus rhesus*.—A communication was read from Mr. W. H. Hudson, containing remarks on the birds of the Rio Negro of Patagonia, as observed during a recent visit to that locality. To this was added an appendix, by Mr. Selater, giving a scientific account of Mr. Hudson's collections.—A communication was read from Mr. R. Swinhoe, containing descriptions of two new pheasants (*Phasianus ellioti* and *Pucrasia darwini*) and a new *Garrulax* (*G. picticollis*) from the vicinity of Ningpo, China.—A paper by Mr. F. Moore was read containing the descriptions of a large number of new species of Indian Lepidoptera.—Mr. E. W. H. Holdsworth read notes on a Cetacean observed on the west coast of Ceylon, remarkable for possessing a long, straight dorsal fin, and known to the natives as the "Palmyra fish."—Dr. A. Günther read a paper on a collection of reptiles and amphibians made at Metang, in the district of Sarawak, Borneo; to which was added a synopsis of the known species of these classes hitherto recorded from that island. These were stated to be altogether 153 in number.—Sir Victor Brooke, Bart., gave a description of a supposed new species of gazelle from Ugogo in Eastern Africa, which he proposed to designate *Gazella granti*.

Linnean Society, April 18.—Mr. G. Bentham, president, in the chair. Mr. M. E. Grant-Duff, M.P., was elected a fellow.—The President announced the death of Prof. v. Mohl, one of the foreign members of the society.—Prof. Oliver described four new genera of plants recently received at the Kew Herbarium. 1. A new genus of Begoniaceae, from New Grenada, of special interest, as the order at present consists only of the large genus *Begonia*, and another monotypic one from the Sandwich Isles. It resembles in habit the series of *Begonia* with thin membranous leaves not cordate at the base; but is very aberrant from the typical genus in possessing a single monophyllous perianth, and being monococious, the male flowers possessing only four stamens, which are apparently didynamous, and give the plant an external resemblance to Gesneraceae, the ovary, however, is that of typical *Begonia*. Prof. Oliver gives this new genus the name *Begoniella*. It does not appear to throw any light on the difficult affinities of the order. The three other genera are from Dr. Maingay's collection from the Malay Peninsula. The first is a new genus of Hamamelidæ, *Maingaya*, in which the calyx is perfectly closed in the bud, and afterwards ruptured. The order is of interest as going back at least to the Miocene period, and still existing in both hemispheres. The two other new genera belong to the order

Olacineæ. The first, *Ctenolophon*, is one of the few genera of the order with opposite leaves. The second, *Pteleocarpa*, includes two species from Malacca and Borneo.—Prof. Thibaut Dyer on the Assam tea-plant. The Chinese tea-plant is not known in the wild state. The Assam tea-plant may be its indigenous form, but presents well-marked differences.—Dr. Braithwaite on *Zoopstis*, Hook. and Tayl., a genus of Hepaticæ.

Chemical Society, April 18.—The president, Dr. Frankland, F.R.S., in the chair.—The secretary read two papers by Mr. E. A. Letts, "On benzyl isocyanate and cyanurate," and "On a compound of sodium and glycerine."—Prof. Hunley, of Kiel, who spoke in German, gave an account of a new method of determining the carbonic acid in sea-water, and of an apparatus for collecting the water at great depths, which could be immersed to the required distance below the surface, and then closed by means of stop-cocks. These are turned by powerful springs released at the proper moment by an electro-magnet.—Dr. E. T. Thorpe followed with notes on the action of phosphorus pentasulphide on tetrachloride of carbon, and on the degree of solubility of silver chloride in strong nitric acid.—Dr. Hofmann, F.R.S., then gave a brief account of the new phosphorus bases, which he had recently obtained by the action of alcoholic iodides on iodide of phosphonium on the presence of zinc oxide, and illustrated his remarks by several striking experiments.

Mathematical Society, April 11.—Prof. Cayley, F.R.S., vice-president, in the chair.—Prof. Cayley gave an account of a paper "On the Mechanical Exhibition of certain Sextic Curves."—Mr. Roberts then described an apparatus for the description of such curves as had been alluded to by Prof. Cayley; and further drew attention to an analogous manner in which certain surfaces of the fourth degree may be generated.—A discussion followed upon some questions proposed in which the chairman, Prof. Crofton, Messrs. Cotterill, Merrifield, Sprague, and others took part.

Photographic Society, April 9.—James Glaisher, F.R.S., in the chair. A paper on Merget's Mercury-Printing Process was read, and some photographs produced by its means were shown. The photographic image is produced by the reduction of silver, or other precious metal, salts, by mercuric vapour, which has been in the first place collected upon a cliché obtained in the camera. The process is not yet sufficiently elaborated to be of much practical value.—A paper "On the Photographic Image upon a Bichromate Film" was read by Mr. H. Baden Pritchard, who demonstrated by a few examples the rapidity with which the image, once started by light upon a carbon tissue, continues to acquire vigour after the latter has been withdrawn from the action of the solar rays.

Victoria Institute, April 15.—The Rev. J. G. Wood "On the Rationality of the Lower Animals." He gave various instances of the instinct and rationality of different animals inhabiting various portions of the globe, and dwelt principally on the latter, which he considered many animals to possess, though in a very limited sense. An interesting discussion followed, in which Captain Petrie pointed out that had the animal creation no rationality, or rather intelligence, it would be without an attribute, which helped to make it more subservient to man's wants. The Rev. C. A. Roe pointed out that the reasoning powers of man were different from the reason possessed by animals, which was exceedingly limited, and of a peculiar nature.

MANCHESTER

Literary and Philosophical Society, March 5.—E. W. Binney, F.R.S., president, in the chair. "On Changes in the Distribution of Barometric Pressure, Temperature, and Rainfall under different Winds during a Solar Spot Period," by Joseph Baxendell, F.R.A.S.—"Further Experiments on the Rupture of Iron Wire," by Mr. John Hopkinson.

Physical and Mathematical Section, November 7, 1871.—Alfred Brothers, F.R.A.S., vice-president, in the chair. "On Changes in the Distribution of Barometric Pressure, Temperature, and Rainfall, under different winds, during a Solar Spot Period," by Joseph Baxendell, F.R.A.S.

December 5, 1871.—Mr. Thomas Carrick in the chair. "On the Distribution of Rainfall under different Winds, at St. Petersburg, during a Solar Spot Period," by Joseph Baxendell, F.R.A.S.

February 27.—E. W. Binney, F.R.S., vice-president of the section, in the chair. "Results of Observations, registered at

Eccles, on the Direction and Range of the Wind for 1869, as made by an Automatic Anemometer for Pressure and Direction," by Thomas Mackereith, F.R.A.S.—"On Black Bulb Solar Radiation Thermometers exposed in various Media," by G. V. Vernon, F.R.A.S.—Note "On the Relative Velocities of different Winds, at Southport, and Eccles, near Manchester," by Joseph Baxendell, F.R.A.S.

CAMBRIDGE

Philosophical Society, March 11.—Mr. E. H. Morgan, of Jesus College, and Mr. J. W. Cartmell, of Christ's College, were elected fellows. The following communications were read:—(1) By Mr. Hiern, "A monograph of the *Ebenacea*." This elaborate paper will shortly appear in the Society's Transactions. (2) By Dr. Bacon, "The influence of human generations on the production of insanity." The author brought forward statistics to prove that insanity was proportionate to poverty—the greatest number of insane persons being found in the poorest districts. Hence he considered that ameliorating the condition of the people was of the first importance in the attack on this disease. (3) By Mr. J. W. L. Glaisher, "Supplement to a table of Bernoulli's numbers."

EDINBURGH

Royal Society, March 18.—Sir Robert Christison, Bart., president, in the chair.—"On the Extraction of a Square Root of a Matrix of the Third Order," by Prof. Cayley.—"Second Note on the Strain-Function," by Prof. Tait.—"Note on the Rate of Cooling at High Temperatures," by Prof. Tait.—"Notice of a Whinstone Boulder with Artificial Markings and Grooves on it," by Mr. D. Milne Home, LL.D.—"Notice of the Fruiting of the Ipecacuan Plant in the Edinburgh Royal Botanic Garden," by Prof. Balfour.

Royal Physical Society, March 27.—Mr. C. W. Peach, president, in the chair. Note on the occurrence of the Hoopoe (*Upupa Epops*) at Freugh, Stoneykirk, Wigtownshire, by Rev. George Wilson. The specimen, a male in perfect plumage, was shot by Mr. Cunningham on March 16.—Notice of a species of Mason Ant on the Isle of May, by James M'Bain, M.D. Dr. M'Bain visited the Isle of May on Feb. 16, and obtained specimens of the ants, with eggs, larvae, and attendant aphides. The ants since then had been kept in glass vessels, and one of the artificial Formicariæ was exhibited to the Royal Physical Society. There appeared to be two species of ants in the colonies, one of which corresponded with the specific characters of the yellow ant, *Formica flava*, and, being in doubt as to the specific name of the brown ant, specimens of each were sent to the British Museum. Mr. F. Smith, a distinguished authority on the *Hymenoptera*, stated that "there are two species and two genera in the quill—one is *Formica flava*, the other is *Myrmica ruginodes*. The *Formica* is at once known by its single lamina, node (or scale) between thorax and abdomen; the *Myrmica* has two nodes, and also a sting. These ants commonly occupy opposite sides of the same hillock."—"On the Vegetable and Animal Life found in Natural Waters," by Dr. Stevenson Macadam.—Notes of a Tour in Auvergne, with an exposition of some of the most illustrative minerals of Central France; and remarks on the nomenclature of some species of the family *Mytilidae*, by Mr. D. Grieve.—Analysis of "The Albert Limestone," Balmoral, by Mr. J. Falconer King.—Prof. Walley exhibited a curious example of malformation in a newly-born calf. The upper part of the skull was undeveloped, it had no apparent forelegs, only rudimentary and imperfect hindlegs, a rudimentary tail, and was otherwise imperfectly developed.

GLASGOW

Geological Society, March 21.—Mr. James Thomson, vice-president, in the chair.—"Some Recently-exposed Sections in the Paisley Clay-beds, and their Relation to the Glacial Period," by the Rev. William Fraser, of Paisley. These clays presented the following general order:—(1) Underlying all was the old boulder clay or till, the conditions of which were altogether unfavourable to life. It represented a cold, bleak, and in part tumultuary period. (2) Immediately above this was a laminated clay, whose texture was in every way distinct from the preceding. It was generally shell-less and stoneless and beautifully laminated, the structure being at times so regular as to resemble the edge of a closed book, and specimens kept for a year or two have shown a texture and taken a polish like jasper. (3)

Above the laminated clay, which was useful in brickmaking, there occurs a thick bed in which shells of arctic and boreal types are found—*Tellina proxima*, *Panopæa norvegica*, *Pecten islandicus*, *Cyprina islandica*, and others too numerous to specify. Geologists loved the layer for its shells, which the brick-field proprietors regarded with an intense dislike. (4.) Next in order is the clay chiefly used in brickmaking. In it the glacial shells are not to be found; the last which disappears is the *Cyprina islandica*. But in these clays, indeed in all above the laminated clay, small and large stones, up to boulders of several tons in weight, are abundant. In some instances they bear longitudinal scratches, but they are deposited so irregularly that their lines lie in every direction; showing that while the origin of the lines or striae was to be ascribed to the period and the processes of the boulder clay, the transport and distribution of the materials was connected with subsequent movements and the melting of floating masses of ice. At the close of the formation of this clay, and on its surface, appeared patches of a well-known shell, *Mytilus edulis*, the common mussel. (5.) Closing the series is a covering of varying thickness, and composed of various materials. There sometimes appeared near the surface a coarsely laminated clay, which had occasionally been mistaken by observers for the more finely laminated clay to be found at the commencement of the series. A long period, however, must have intervened between the two, and he suggested a careful scrutiny as to the facts connected with these two distinct clays.

DUBLIN

Royal Geological Society of Ireland, February 14.—Francis M. Jennings, F.C.S., in the chair. The honorary secretary, Dr. Alexander Macalister, read the annual report of the council. The following officers for the ensuing year were then elected by ballot:—President—Dr. Alex. Macalister. Vice-presidents—Earl of Enniskillen, Colonel Meadows Taylor, J. Emerson Reynolds, Rev. H. Lloyd, F.R.S., and Sir Richard Griffith, Bart. Treasurers—William Andrews and Dr. Samuel Downing. Secretaries—Rev. S. Haughton, F.R.S., and Edward Hull, F.R.S. Council—Sir Robert Kane, F.R.S., Alphonse Gages, B. B. Stoney, W. Frazer, Dr. Alex. Carte, W. H. S. Westropp, C. R. C. Tichborne, F.C.S., Rev. Maxwell Close, Francis M. Jennings, F.C.S., Dr. Ramsay H. Traquair, Dr. J. Barker, J. Ball Greene, W. H. Dailly, F.G.S., W. Ogilby, F.G.S., and R. A. Gray.—Prof. Hull, Director of the Geological Survey of Ireland, read a paper on a remarkable fault in the New Red sandstone of Whiston, Cheshire. The position of this fault is marked on the geological survey maps of Lancashire (one inch map 80 N.W.) as forming the boundary between the little isolated tract of coal measures, one mile west of Rainhill Station and the New Red sandstone. The fault ranges in a nearly meridional direction, and on the west the upper coal measures, with spirorbis limestone (first discovered by Mr. Binney, F.R.S.), are brought to the surface, and on the east the upper mottled sandstone of the Bunter division of the Trias. The Corporation of St. Helen's, in order to increase the water supply of the borough, commenced sinking a well, on Mr. Hull's recommendation, at a distance of 200 yards from the fault in the New Red sandstone close to Cumber Lane Bridge. This well was carried down 75 yards, and from the bottom a bore hole, 18in. diameter, was driven 35 yards farther; but at 104 yards from the surface it passed through the fault, and entered hard micaceous sandstone of a purple colour belonging to the upper coal-measures. As the horizontal distance from the outcrop of the fault where it crosses the railway is 200 yards, and the depth 104 yards, it appears that the slope of the fault is about two horizontal to one vertical, or 28° from the horizontal. The usual slope of the faults in South Lancashire being two vertical to one horizontal, such a result was unexpected, and as the thickness of New Red sandstone was thus reduced below the calculated amount the quantity of water obtained (about 400,000 gallons per day) was consequently much less than that required and anticipated.

February 22.—A paper was read from Mr. G. H. Kinahan "On the Formation of Valleys and Lake-basins, with special reference to Lochlomond." The author dissented from the views which had been put forth by several eminent geologists as to sub-aerial denudation; and held that the principal valleys both in Scotland and Ireland lay along lines of faults or fissures

* This site was selected, not as being the best for water supply, but the best available.

in the subjacent rocks. In the highlands of Scotland, so far as he had observed, there was not a valley, ravine, or lake-basin unconnected with a break or fault in the strata; and instanced particularly the Caledonian Canal, Loch Awe, Glencoe, Loch Fyne, and Lochlomond. He considered the deep parts of the latter lake were due to the meeting or crossing of two or more breaks, where consequently the rocks were fractured to a greater extent. Some of the dislocations, he was inclined to think, had been post-glacial.

PARIS

Academy of Sciences, April 15.—M. de Saint-Venant read a memoir on the intensity of the forces capable of deforming ductile cylindrical blocks placed under various conditions.—M. J. Boussinesq read a memoir on the influence of the centrifugal forces upon the varied permanent flow of water in prismatic channels of great width.—M. de Saint-Venant presented a note by M. E. Combes on a process of integration by successive approximations of the equation

$$4 \left(\frac{d^2 \psi}{dx dz} \right)^2 + \left(\frac{d^2 \psi}{dx^2} - \frac{d^2 \psi}{dz^2} \right)^2 = 4 K^2$$

in plastic dynamics.—MM. P. A. Favre and C. A. Valson presented a continuation of their researches upon crystalline dissociation. This paper contains the first part of their investigations on the alums.—A note by M. Lecqz de Boisbaudran on the spectrum of the vapour of water. The spectrum was obtained by passing an induction current through a tube filled with rarefied aqueous vapour; the spectrum consists of white stratifications, the light of which is resolved into four principal lines.—Several papers relating to auroras were read, including a note by M. Chapelas on polar lights observed in Paris on the evening of April 10; one by M. Tarry, communicated by M. Le Verrier, on the prevision of magnetic auroras by means of terrestrial currents, as applied to the aurora of April 10 by M. Sureau; a general investigation of auroras by M. Heis, including a long list of parallel occurrences of such phenomena in the northern and southern hemispheres during the years 1870 and 1871; and a note by M. Linder on the theory of auroras, in which the author concludes that they are electro-magnetic phenomena which have their seat chiefly in the upper regions of the atmosphere.—M. Loewy presented a note on the discovery of two new planets, 119 and 120, one observed in Paris on April 9 by M. Paul Henry, the other at Marseilles on April 10 by M. Borely. The positions of these planets on April 11-13 are given.—M. Berthelot read a note on the heat of formation of the oxygenated compounds of nitrogen.—M. A. Gillot presented a claim of priority with respect to a paper read by M. Gruner on January 22 on the action of oxide of carbon on iron and its oxides.—M. Cahours presented a note by MM. L. Dusart and C. Bady on the phenoles.—M. Bous-singault presented a note by M. A. Muntz on the statics of the cultivation of hops, containing a statement of the elements assimilated by the hop plants grown upon thirty-eight ares, and upon one hectare of land at Wörth.—A note by M. C. van Bamberke on the first effects of fecundation upon the ova of fishes and on the origin and interpretation of the mucous or glandular lamella in the osseous fishes was presented by M. de Quatrefages. The author stated, as the result of his researches, that under the influence of fecundation the germinal disc of the egg in osseous fishes divides into two layers, of which the upper one becomes segmented, whilst the lower one forms an intermediate layer between the segmented blastoderm and the vitelline sphere, and accompanies the former in its development around the latter. He regards the thin central portion of this intermediate layer as the homologue of the mucous lamella.—M. A. Gaudry read a paper on the fossil animals of the Léberon in Vaulcuse. These fossils are chiefly mammalian, and present a remarkable analogy to those of the Miocene deposits of Pikermi in Attica, investigated some years since by the author.—M. A. Brongniart presented a note by M. de Saporta "On the more precise determination of certain Jurassic Coniferous Genera by Observation of their Fruits." The genera here referred to are *Brachyphyllum*, *Pachyphyllum*, *Echinostrobus*, *Cunninghamia*, *Widdringtonia*, *Palaeocyparis* (a new genus proposed for some species described as belonging to *Thuyites*), and *Phyllostrobus* (a new genus allied to *Thuja*).—M. de Quatrefages communicated a note by MM. E. Massenet, P. Lalande, and Cartailhac "On the Discovery of a Human Skeleton of the Reindeer period at Laugerie-Basse in the Dordogne."—M. A. Milne-Edwards read some researches upon fossil birds, containing a sort of summary of the results of

his long-continued investigation.—M. L. V. Turquan submitted to the judgment of the Academy the description of an apparatus for indicating the presence of fire-damp in mines.

BOOKS RECEIVED

FOREIGN.—(Through Williams and Norgate.)—Anatomische-systematische Beschreibung der Alcyonarien, 1^{te} Abtheilung, die Pennatuliden. A. Kölliker.—Morphologie u. Entwickelungs-geschichte des Pennatulidenstammes nebst allgemeinen Betrachtungen zur Descendenzlehre. A. Kölliker.—Beitrag zur Anatomie der Plattwürmer: Sommer. Landou. Index der Petrographie u. Stratigraphie der Schweiz u. ihrer Umgebungen: B. Studer.—Geschichte der Himmelskunde nach ihrem gesammten Umfange, Paris 1-3: J. H. v. Mädler.—Hydra, eine anatomische entwickelungs-geschichtliche Untersuchung: Dr. N. Kleinberg.

DIARY

THURSDAY, April 25.

ROYAL SOCIETY, at 8.30.—On a Supposed Periodicity in the Elements of Terrestrial Magnetism, with a Period of 264 Days: The President.—Contributions to Formal Logic: A. J. Ellis, F.R.S.

LONDON INSTITUTION, at 7.30.—On the Effects of Certain Faults of Vision on Painting, with special reference to the Works of Turner and Mulready: Dr. Liebreich.

ROYAL INSTITUTION, at 3.—On Heat and Light: Prof. Tyndall, F.R.S.

FRIDAY, April 26.

ROYAL INSTITUTION, at 9.—On the Genius and Character of the Modern Greek Language: Prof. Blackie, F.R.S.E.

QUEKETT MICROSCOPICAL CLUB, at 8.

SATURDAY, April 27.

ROYAL INSTITUTION, at 3.—The Star-Depths: R. A. Proctor.

GOVERNMENT SCHOOL OF MINES, at 8.—On Geology: Dr. Cobbold.

SUNDAY, April 28.

SUNDAY LECTURE SOCIETY, at 4.—On Geographical Influences on History: Prof. John Venn, M.D.

MONDAY, April 29.

ZOOLOGICAL SOCIETY, at 1.—Anniversary Meeting.

LONDON INSTITUTION, at 4.—Elementary Botany, with special reference to the Classification of Plants: Prof. Bentley, F.L.S.

TUESDAY, April 30.

ROYAL INSTITUTION, at 2.—On the Development of Belief and Custom amongst the Lower Races of Mankind: E. B. Tylor, F.R.S.

WEDNESDAY, May 1.

ROYAL INSTITUTION, at 2.—On the Development of Belief and Custom amongst the Lower Races of Mankind: E. B. Tylor, F.R.S.

SOCIETY OF ARTS, at 8.—On Telegraphy without Insulation, the means of cheapening International Communication: H. Highton.

MICROSCOPICAL SOCIETY, at 8.

THURSDAY, May 2.

ROYAL SOCIETY, at 8.30.

SOCIETY OF ANTIQUARIES, at 8.30.

PROFESSOR OF ARTS, at 8.—On *Alibertia edulis*: Señor Correa de Mello.

CHEMICAL SOCIETY, at 8.

ROYAL INSTITUTION, at 3.—On Heat and Light: Prof. Tyndall, F.R.S.
